Abstract

We propose a modular extension of backpropagation for the computation of block-diagonal approximations to various curvature matrices of the training objective (in particular, the Hessian, generalized Gauss-Newton, and positive-curvature Hessian). The approach reduces the otherwise tedious manual derivation of these matrices into local modules, and is easy to integrate into existing machine learning libraries. Moreover, we develop a compact notation derived from matrix differential calculus. We outline different strategies applicable to our method. They subsume recently-proposed block-diagonal approximations as special cases, and are extended to convolutional neural networks in this work.

1 Introduction

Gradient backpropagation is the central computational operation of contemporary deep learning. Its modular structure allows easy extension across network architectures, and thus automatic computation of gradients given the computational graph of the forward pass (for a review, see Baydin et al., 2018). But optimization using only the first-order information of the objective’s gradient can be unstable and slow, due to “vanishing” or “exploding” behaviour of the gradient. Incorporating curvature, second-order methods can avoid such scaling issues and converge in fewer iterations. Such methods locally approximate the objective function $E$ by a quadratic $E(x) + \delta x^\top (x_s - x) + \frac{1}{2} (x_s - x)^\top C(x_s - x)$ around the current location $x$, using the gradient $\delta x = \partial E/\partial x$ and a positive semi-definite (PSD) curvature matrix $C$ — the Hessian of $E$ or approximations thereof. The quadratic is minimized by

$$x_s = x + \Delta x \quad \text{with} \quad \Delta x = -C^{-1} \delta x.$$  

Computing the update step requires that the $C \Delta x = -\delta x$ linear system be solved. To accomplish this task, providing a matrix-vector multiplication with the curvature matrix $C$ is sufficient.

Approaches to second-order optimization: For some curvature matrices, exact multiplication can be performed at the cost of one backward pass by automatic differentiation (Pearlmutter, 1994; Schraudolph, 2002). This matrix-free formulation can then be leveraged to solve (1) using iterative solvers such as the method of conjugate gradients (CG) (Martens, 2010). However, since this linear solver can still require multiple iterations, the increased per-iteration progress of the resulting optimizer might be compensated by increased computational cost. Recently, a parallel version of Hessian-free optimization was proposed in (Zhang et al., 2017), which only considers the content of Hessian sub-blocks along the diagonal. Reducing the Hessian to a block diagonal allows for parallelization, tends to lower the required number of CG iterations, and seems to improve the optimizer’s performance.

There have also been attempts to compute parts of the Hessian in an iterative fashion (Mizutani and Dreyfus, 2008). Storing these constituents efficiently often requires an involved manual analysis of the Hessian’s structure, leveraging its outer-product form in many scenarios (Naumov, 2017; Bakker et al., 2018). Recent works developed different block-diagonal approximations (BDA) of curvature matrices that provide fast multiplication (Martens and Grosse, 2015; Grosse and Martens, 2016; Botev et al., 2017; Chen et al., 2018). These works have repeatedly shown that, empirically, second-order information can improve the training of
The first two contributions can be understood as an explicit formulation of well-known tricks for fast multiplication by curvature matrices using automatic differentiation (Pearlmutter, 1994; Schraudolph, 2002). However, we also address a new class of curvature matrices, the positive-curvature Hessian (PCH) introduced in Chen et al. (2018). Our solutions to the latter two points are generalizations of previous works (Botev et al., 2017; Chen et al., 2018) to the fully modular case, which become accessible due to the first contribution. They represent additional modifications to make the scheme computationally tractable and obtain curvature approximations with desirable properties for optimization.

2 Notation

We consider feedforward neural networks composed of \( \ell \) modules \( f^{(i)}, i = 1, \ldots, \ell \), which can be represented as a computational graph mapping the input \( z^{(0)} = x \) to the output \( z^{(\ell)} \) (Figure 1). A module \( f^{(i)} \) receives the parental output \( z^{(i-1)} \), applies an operation involving the network parameters \( \theta^{(i)} \), and sends the output \( z^{(i)} \) to its child. Thus, \( f^{(i)} \) is of the form \( z^{(i)} = f^{(i)}(z^{(i-1)}, \theta^{(i)}) \). Typical choices include element-wise nonlinear activation without any parameters and affine transformations \( z^{(i)} = W^{(i)} z^{(i-1)} + b^{(i)} \) with parameters given by the weights \( W^{(i)} \) and the bias \( b^{(i)} \). Affine and activation modules are usually considered as a single conceptual unit, one layer of the network. However, for backpropagation of derivatives it is simpler to consider them separately as two modules.

Given the network output \( z^{(\ell)}(x, \theta^{(1:\ell)}) \) of a datum \( x \) with label \( y \), the goal is to minimize the expected risk of the loss function \( E(z^{(\ell)}, y) \). Under the framework of empirical risk minimization, the parameters are tuned to optimize the loss on the training set \( Q = \{(x, y)_{i=1}^{N}\} \),

\[
\min_{\theta^{(1:\ell)}} \frac{1}{|Q|} \sum_{(x,y) \in Q} E(z^{(\ell)}(x), y). \tag{2}
\]

In practice, the objective is typically further approximated stochastically by drawing a mini-batch \( B \subset Q \) from the training set. We will treat both scenarios...
without further distinction, since the structure relevant to our purposes is that Equation (2) is an average of terms depending on individual data points. Quantities for optimization, be it gradients or second derivatives of the loss with respect to the network parameters, can be processed in parallel, then averaged.

3 Main contribution

First-order auto-differentiation for a custom module requires the definition of only two local operations, forward and backward, whose outputs are propagated along the computation graph. This modularity facilitates the extension of gradient backpropagation by new operations, which can then be used to build networks by composition. To illustrate the principle, we consider a single module from the network of Figure 1, depicted in Figure 2, in this section. The forward pass \( f(x, \theta) \) maps the input \( x \) to the output \( z \) by means of the module parameters \( \theta \) (to simplify notation, we drop layer indices). All quantities are assumed to be vector-shaped (tensor-valued quantities can be vectorized, see Section A of the Supplements). Optimization requires the gradient of the loss function with respect to the parameters, \( \partial E(\theta)/\partial \theta = \delta \theta \). We will use the shorthand

\[
\delta = \delta E(\cdot) / \partial \text{vec}(\cdot). 
\]

During gradient backpropagation the module receives the loss gradient with respect to its output, \( \delta z \), from its child. The backward operation computes gradients with respect to the module parameters and input, \( \delta \theta \) and \( \delta x \) from \( \delta z \). Backpropagation continues by sending the gradient with respect to the module’s input to its parent, which proceeds in the same way (see Figure 1). By the chain rule, gradients with respect to an element of the module’s input can be computed as

\[
\delta x_i = \sum_j \partial z_j / \partial x_i \partial z_i. 
\]

The vectorized version is compactly written in terms of the Jacobian matrix

\[
\mathbf{D}_z(x) = \partial z(x) / \partial x, 
\]

which contains all partial derivatives of \( z \) with respect to \( x \). The arrangement of partial derivatives is such that \( \mathbf{D}_z(x)_{j,i} = \partial z_j(x) / \partial x_i, \) i.e.

\[
\delta x = [\mathbf{D}_z(x)]^\top \delta z. 
\]

Analogously, the parameter gradients are given by \( \delta \theta_i = \sum_j \partial \theta_i / \partial \theta_j \partial z_j, \) i.e. \( \delta \theta = [\mathbf{D}_\theta(\theta)]^\top \delta z, \) which reflects the symmetry of both \( x \) and \( \theta \) acting as input to the module. Implementing gradient backpropagation thus requires multiplications by (transposed) Jacobians.

We can apply the chain rule a second time to obtain expressions for second-order partial derivatives of the loss function \( E \) with respect to elements of \( x \) or \( \theta \),

\[
\frac{\partial^2 E(x)}{\partial x_i \partial x_j} = \frac{\partial}{\partial x_j} \left( \sum_k \frac{\partial z_k}{\partial x_i} \delta z_k \right) = \sum_{k,l} \frac{\partial z_k}{\partial x_i} \frac{\partial^2 E(z)}{\partial z_l \partial x_j} \delta z_l + \sum_k \frac{\partial^2 z_k}{\partial x_i \partial x_j} \delta z_k, 
\]

by means of \( \partial / \partial x_j = \sum_l \partial z_l / \partial x_j \partial z_l \) and the product rule. The first term of Equation (5) propagates curvature information of the output further back, while the second term introduces second-order effects of the module itself. Using the Hessian matrix \( \mathbf{H}(x) = \partial^2 E(x)/\partial x \partial x^\top \) of a scalar function with respect to a vector-shaped quantity \( x \), the Hessian of the loss function will be abbreviated by

\[
\mathbf{H} = \frac{\partial^2 E(\cdot)}{\partial \text{vec}(\cdot)^\top \partial \text{vec}(\cdot)}. 
\]

which results in the matrix version of Equation (5),

\[
\mathbf{H}_x = [\mathbf{D}_z(x)]^\top \mathbf{H}_z [\mathbf{D}_z(x)] + \sum_k [\mathbf{H}_z(x)] \delta z_k. 
\]

Note that the second-order effect introduced by the module itself via \( \mathbf{H}_z(x) \) vanishes if \( f_k(x, \theta) \) is linear in \( x \). Because the layer parameters \( \theta \) can be regarded as inputs to the layer, they are treated in exactly the same way, replacing \( x \) by \( \theta \) in the above expression.

Equation (7) is the central functional expression herein, and will be referred to as the Hessian backpropagation (HBP) equation. Our suggested extension of gradient backpropagation is to also send the Hessians \( \mathbf{H}_\theta, \mathbf{H}_z \) by means of Equation (7), and forward the Hessian with respect to its input \( \mathbf{H}_x \) to the parent module which proceeds likewise. In this way, backprop of gradients.
The computations required in Equation (7) depend which represents one key aspect of our work. The second term of (7) needs special treatment though. The Hessian products can reuse multiplication by the (transposed) Jacobian cursively in terms of the composites’ lower-order derivatives. This corresponds to BDAs of the Hessian that ignore second-order partial derivatives of parameters in different modules. Figure 3 shows the data flow. The computations required in Equation (7) depend only on local quantities that are, mostly, already being computed during gradient backpropagation.¹

Before we proceed, we highlight the following aspects:

- The BDA of the Hessian need not be PSD. But our scheme can be modified to provide PSD curvature matrices by projection onto the positive semi-definite cone (see Subsection 3.1).
- Instead of evaluating all matrices during backpropagation, we can define matrix-vector products recursively. This yields exact curvature matrix products with the block diagonals of the Hessian, the generalized Gauss-Newton (GGN) matrix and the PCH. Products with the first two matrices can also be obtained by use of automatic differentiation (Pearlmutter, 1994; Schraudolph, 2002). We also get access to the PCH which, in contrast to the GGN, considers curvature information introduced by the network (see Subsection 3.1).² For standard neural networks, only second derivatives of nonlinear activations have to be stored compared to gradient backpropagation.
- There are approaches (Botev et al., 2017; Chen et al., 2018) that propagate matrix representations back through the graph in order to save repeated computations in the curvature matrix-vector product. The size of the matrices $H_z^{(i)}$ passed between layer $i + 1$ and $i$ scales quadratically in the number of output features of layer $i$. For convolutional layers and in case of batched input data, the dimension of these quantities exceeds computational budgets. In line with previous schemes (Botev et al., 2017; Chen et al., 2018), we introduce additional approximations for batch learning in Subsection 3.2. A connection to existing schemes is drawn in the Supplements B.4.

HBP can easily be integrated into current machine learning libraries, so that BDAs of curvature information can be provided automatically for novel or existing second-order optimization methods. Such methods have repeatedly been shown to be competitive with first-order methods (Martens and Grosse, 2015; Grosse and Martens, 2016; Botev et al., 2017; Zhang et al., 2018).

Relationship to matrix differential calculus: To some extent, this paper is a re-formulation of earlier results (Martens and Grosse, 2015; Botev et al., 2017; Chen et al., 2018) in the framework of matrix differential calculus (Magnus and Neudecker, 1999), leveraged to achieve a new level of modularity. Matrix differential calculus is a set of notational rules that allow a concise construction of derivatives without the heavy use of indices. Equation (7) is a special case of the matrix chain rule of that framework. A more detailed discussion of this connection can be found in Section A of the Supplements, which also reviews definitions generalizing the concepts of Jacobian and Hessian in a way that preserves the chain rule. The elementary building block of our procedure is a module as shown in Figure 2. Like for gradient backprop, the operations required for HBP can be tabulated. Table 1 provides a selection of common modules. The derivations, which again leverage the matrix differential calculus framework, can be found in Supplements B, C, and D.

3.1 Obtaining different curvature matrices

The HBP equation yields exact diagonal blocks $H\theta^{(1)}, \ldots, H\theta^{(\ell)}$ of the full parameter Hessian. They can be of interest in their own right for analysis of the loss function, but are not generally suitable for second-order optimization in the sense of (1), as they need

---

¹ By Faà di Bruno’s formula (Johnson, 2002) higher-order derivatives of function compositions are expressed recursively in terms of the composites’ lower-order derivatives.

²Implementations of HBP for exact matrix-vector products can reuse multiplication by the (transposed) Jacobian provided by many machine learning libraries. The second term of (7) needs special treatment though.
Table 1: Hessian backpropagation for common modules used in feedforward networks. \( I \) denotes the identity matrix. We assign matrices to upper-case (\( W, X, \ldots \)) and tensors to upper-case sans serif symbols (\( W, X, \ldots \)).

neither be PSD nor invertible. For application in optimization, HBP can be modified to yield semi-definite BDAs of the Hessian. Equation (7) again provides the foundation for this adaptation, which is closely related to the concepts of KFRA (Botev et al., 2017), BADA-PCH (Chen et al., 2018), and, under certain conditions, KFAC (Martens and Grosse, 2015). We draw their connections by briefly reviewing them here.

**Generalized Gauss-Newton matrix:** The GGN emerges as the curvature matrix in the quadratic expansion of the loss function \( E(z^{(\ell)}) \) in terms of the network output \( z^{(\ell)} \). It is also obtained by linearizing the network output \( z^{(\ell)}(\theta, x) \) in \( \theta \) before computing the loss Hessian (Martens, 2014), and reads

\[
G(\theta) = \frac{1}{|Q|} \sum_{(x,y)\in Q} \begin{bmatrix} Dz^{(\ell)}(\theta) \end{bmatrix}^T \mathcal{H}E(z^{(\ell)}) \begin{bmatrix} Dz^{(\ell)}(\theta) \end{bmatrix}.
\]

To obtain diagonal blocks \( G(\theta^{(i)}) \), the Jacobian can be unrolled by means of the chain rule for Jacobians (Supplements, Theorem A.1) as \( Dz^{(\ell)}(\theta^{(i)}) = \begin{bmatrix} Dz^{(\ell)}(z^{(\ell-1)}) \end{bmatrix} \begin{bmatrix} Dz^{(\ell-1)}(\theta^{(i)}) \end{bmatrix} \ldots \). Continued expansion shows that the Hessian \( \mathcal{H}E(z^{(\ell)}) \) of the loss function with respect to the network output is propagated back through a layer by multiplication from left and right with its Jacobian. This is accomplished in HBP by ignoring second-order effects introduced by modules, that is by setting the Hessian of the module function to zero, therefore neglecting the second term in Equation (7). In fact, if all activations in the network are piecewise linear (e.g. ReLUs), the GGN and Hessian blocks are equivalent. Moreover, diagonal blocks of the GGN are PSD if the loss function is convex (and thus \( \mathcal{H}E(z^{(\ell)}) \) is PSD). This is because blocks are recursively left- and right-multiplied with Jacobians, which does not alter the definiteness. Hessians of the loss functions listed in Table 1 are PSD. The resulting recursive scheme has been used by Botev et al. (2017) under the acronym KFRA to optimize convex loss functions of fully-connected neural networks with piecewise linear activation functions.

**Positive-curvature Hessian:** Another concept of positive semi-definite BDAs of the Hessian (that additionally considers second-order module effects) was studied in Chen et al. (2018) and named the PCH. It is obtained by modification of terms in the second summand of Equation (7) that can introduce concavity during HBP. This ensures positive semi-definiteness since the first summand is semi-definite, assuming the loss Hessian \( \mathcal{H}E(z^{(\ell)}) \) with respect to the network output to be positive semi-definite. Chen et al. (2018) suggest to eliminate negative curvature of a matrix by computing the eigenvalue decomposition and either discard negative eigenvalues or cast them to their absolute value. This allows the construction of PSD curvature matrices even for non-convex loss functions. In the setting of Chen et al. (2018), the PCH can empirically outperform optimization using the GGN. In usual feedforward neural networks, the concavity is introduced by nonlinear elementwise activations, and corresponds to a diagonal matrix (Table 1). Thus, convexity can be maintained during HBP by either clipping negative values to zero (PCH-clip), or taking their magnitude in the diagonal concave term (PCH-abs).
Fisher information matrix: If the network defines a conditional probability density \( r(y|z^{(t)}) \) on the labels, maximum likelihood learning for the parameterized density \( p_B(y|x) \) will correspond to choosing a negative log-likelihood loss function, i.e. \( E(z^{(t)}, y) = -\log r(y|z^{(t)}) \). Common loss functions like square and cross-entropy loss can be interpreted in this way. Natural gradient methods relying on direct inversion.

In this form, the computational scheme for BDAs of the Fisher resembles the HBP of the GGN. However, instead of propagating back the exact Hessian with respect to the module input, the network’s expected Hessian of the negative log-likelihood under the model’s predictive density is used. Martens and Grosse (2015) use Monte-Carlo sampling to estimate this matrix in their KFAC optimizer. Relations between the Fisher and GGN are discussed in (Pascanu and Bengio, 2013; Martens, 2014); for square and cross-entropy loss, they are equivalent.

3.2 Batch learning approximations

In our HBP framework, exact multiplication by the block of the curvature matrix of parameter \( \theta \) in a module comes at the cost of one gradient backpropagation and one layer output Hessian \( H_z \). If it were possible to have an explicit representation of this matrix in memory, the recursive computations hidden in \( H_z \) could be saved during the solution of the linear system implied by Equation (1). Unfortunately, the size of the backpropagated exact matrices scales quadratically in both the batch size and the number of layer’s output features. However, instead of propagating back the exact Hessian, a batch-averaged version can be used instead to circumvent the batch size scaling (originating from Botev et al. (2017)). In combination with structural information about the parameter Hessian, this strategy is used in Botev et al. (2017); Chen et al. (2018) to further approximate curvature multiplications, using quantities computed in a single backward pass and then kept in memory for application of the matrix-vector product. We can embed these explicit schemes into our modular approach. To do so, we denote averages over a batch \( B \) by a bar, for instance \( 1/|B| \sum_{(x,y) \in B} HE(\theta) = \overline{HE(\theta)} \). The modified backward pass of curvature information during HBP for a module receives a batch average of the Hessian with respect to the output, \( \overline{H_z} \), which is used to formulate the matrix-vector product with the batch-averaged parameter Hessian \( \overline{H_\theta} \). An average of the Hessian with respect to the module input, \( \overline{H_x} \), is passed back. Existing work (Botev et al., 2017; Chen et al., 2018) differs primarily in the specifics of how this batch average is computed. In HBP, these approximations can be formulated compactly within Equation (7). Relations to the cited works are discussed in more detail in the Supplements B.4. The approximations amounting to relations used by Botev et al. (2017) read

\[
\overline{H_x} \approx |Dz(x)|^\top \overline{H_z} |Dz(x)| + \sum_k [H_{z_k}(x)] \delta z_k, \tag{8}
\]

and likewise for \( \theta \). In case of a linear layer \( z(x) = Wx + b \), this approximation implies the relations \( \overline{HW} = x \otimes x^\top \otimes \overline{H_z} \), \( \overline{Hb} = \overline{H_z}z \), and \( \overline{Hx} = W^\top (\overline{H_z})W \). Multiplication by this weight Hessian approximation with a vector \( v \) is achieved by storing \( x \otimes x^\top \otimes \overline{H_z} \) and performing the required contractions \( v \mapsto (x \otimes x^\top \otimes \overline{H_z})v \). Note that this approach is not restricted to curvature matrix-vector multiplication routines only. Kronecker structure in the approximation gives rise to optimization methods relying on direct inversion.

A cheaper approximation, used in Chen et al. (2018),

\[
\overline{H_x} \approx |Dz(x)|^\top \overline{H_z} |Dz(x)| + \sum_k [H_{z_k}(x)] \delta z_k, \tag{9}
\]

leads to the modified relation \( \overline{HW} = \pi \otimes x^\top \otimes \overline{H_z} \) for a linear layer. As this approximation is of the same rank as \( \overline{H_z} \), which is typically small, CG requires only a few iterations during optimization. It avoids large memory requirements for layers with numerous inputs, since it requires \( \pi \) to be stored instead of \( x \otimes x^\top \).

Transformations that are linear in the module parameters (e.g. linear and convolutional layers), possess constant Jacobians with respect to the module input for each sample (see Table 1). Hence, in a network consisting of only these layers, both Equation (8) and (9) yield the same backpropagated Hessians \( \overline{H_x} \). This still leaves the degree of freedom for choosing the approximation scheme in the analogous equations for \( \theta \).

Remark: Both strategies for obtaining curvature matrix BDAs (implicit exact matrix-vector multiplications and explicit propagation of approximated curvature)
are compatible. Regarding the connection to cited works, we note that the maximally modular structure of our framework changes the nature of these approximations and allows a more flexible formulation.

4 Experiments & Implementation

We illustrate the usefulness of incorporating curvature information with the two outlined strategies by experiments with a fully-connected and a convolutional neural network (CNN) on the CIFAR-10 dataset (Krizhevsky, 2009). Following the guidelines of Schneider et al. (2019), the training loss is estimated on a random subset of the training set of equal size as the test set. Each experiment is performed for 10 different random seeds and we show the mean values with shaded intervals of one standard deviation. For the loss function we use cross-entropy. Details on the model architectures and hyperparameters are given in Supplements E.

**Training procedure and update rule:** In comparison to a first-order optimization procedure, the training loop with HBP has to be extended by a single backward pass to backpropagate the batch-averaged or exact loss Hessian. This yields matrix-vector products with a curvature estimate $C(i)$ for each parameter block $\theta(i)$ of the network. Parameter updates $\Delta\theta(i)$ are obtained by applying CG to solve the linear system\(^4\)

$$\left[\alpha I + (1-\alpha)C(i)\right] \Delta\theta(i) = -\delta\theta(i), \quad (10)$$

where $\alpha$ acts as a step size limitation to improve robustness against noise. The CG routine terminates if the ratio of the residual norm and the gradient norm falls below a certain threshold or the maximum number of iterations has been reached. The solution returned by CG is scaled by a learning rate $\gamma$, and parameters are updated by the relation $\theta(i) \leftarrow \theta(i) + \gamma \Delta\theta(i)$.

**Fully-connected network, batch approximations, and sub-blocking:** The flexibility of HBP is illustrated by extending the results in Chen et al. (2018). Investigations are performed on a fully-connected network with sigmoid activations. Solid lines in Figure 4 show the performance of the Newton-style optimizer and momentum SGD in terms of the training loss and test accuracy. The second-order method is capable to escape the initial plateau in fewer iterations.

The modularity of HBP allows for additional parallelism by splitting the linear system (10) into smaller sub-blocks, which then also need fewer iterations of CG. Doing so only requires a minor modification of the parameter Hessian computation by (7). Consequently, we split weights and bias terms row-wise into a specified number of sub-blocks. Performance curves are shown in Figure 4. In the initial phase, the BDA can be split into a larger number of sub-blocks without suffering from a loss in performance. The reduced curvature information is still sufficient to escape the initial plateau. However, larger blocks have to be considered in later stages to further reduce the loss efficiently.

The fact that this switch in modularity is necessary is an argument in favor of the flexible form of HBP, which allows to efficiently realize such switches: For this experiment, the splitting for each block was artificially chosen to illustrate this flexibility. In principle, the splitting could be decided individually for each parameter block, and even changed at run time.

**Convolutional neural network, matrix-free exact curvature multiplication:** For convolutions, the large number of hidden features prohibits backpropagating a curvature matrix batch average. Instead, we use exact curvature matrix-vector products provided within HBP. The CNN possesses sigmoid activations and cannot be trained by SGD (cf. Figure 5a). For comparison with another second-order method, we experiment with a public KFAC implementation (Martens and Grosse, 2015; Grosse and Martens, 2016, see Supplements E for details).

\(^4\)We use the same update rule as Chen et al. (2018) since we extend some of the results shown within this work.
## 5 Conclusion

We have outlined a procedure to compute block-diagonal approximations of different curvature matrices for feedforward neural networks by a scheme that can be realized on top of gradient backpropagation. In contrast to other recently proposed methods, our implementation is aligned with the design of current machine learning frameworks and can flexibly compute Hessian sub-blocks to different levels of refinement. Its modular formulation facilitates closed-form analysis of Hessian diagonal blocks, and unifies previous approaches (Botev et al., 2017; Chen et al., 2018).

Within our framework we presented two strategies: (i) Obtaining exact curvature matrix-vector products that have not been accessible before by auto-differentiation (PCH), and (ii) backpropagation of further approximated matrix representations to save computations during training. As for gradient backpropagation, the Hessian backpropagation for different operations can be derived independently of the underlying graph. The extended modules can then be used as a drop-in replacement for existing modules to construct deep neural networks. Internally, backprop is extended by an additional Hessian backward pass through the graph to compute curvature information. It can be performed in parallel to, and reuse the quantities computed in, gradient backpropagation.
Acknowledgments

The authors would like to thank Frederik Kunstner, Matthias Werner, Frank Schneider, and Agustinus Kristiadi for their constructive feedback on the manuscript, and gratefully acknowledge financial support by the European Research Council through ERC StG Action 757275 / PANAMA; the DFG Cluster of Excellence “Machine Learning - New Perspectives for Science”, EXC 2064/1, project number 390727645; the German Federal Ministry of Education and Research (BMBF) through the Tübingen AI Center (FKZ: 01IS18039A); and funds from the Ministry of Science, Research and Arts of the State of Baden-Württemberg. F. D. is grateful to the International Max Planck Research School for Intelligent Systems (IMPRS-IS) for support.
