Abstract

The article considers smooth optimization of functions on Lie groups. By generalizing NAG variational principle in vector space (Wibisono et al., 2016) to Lie groups, continuous Lie-NAG dynamics which are guaranteed to converge to local optimum are obtained. They correspond to momentum versions of gradient flow on Lie groups. A particular case of $SO(n)$ is then studied in details, with objective functions corresponding to leading Generalized EigenValue problems: the Lie-NAG dynamics are first made explicit in coordinates, and then discretized in structure preserving fashions, resulting in optimization algorithms with faithful energy behavior (due to conformal symplecticity) and exactly remaining on the Lie group. Stochastic gradient versions are also investigated. Numerical experiments on both synthetic data and practical problem (LDA for MNIST) demonstrate the effectiveness of the proposed methods as optimization algorithms (not as a classification method).

1 Introduction

The algorithmic task of optimization is important in data sciences and other fields. For differentiable objective functions, 1st-order optimization algorithms have been popular choices especially for high dimensional problems, largely due to their scalability, generality, and robustness. A celebrated class of them is based on Nesterov Accelerated Gradient descent (NAG; see e.g., (Nesterov, 1983, 2018)), also known as a major way to add momentum to Gradient Descent (GD).

NAGs enjoy great properties such as quadratic decay of error (instead of GD's linear decay) for convex but not strongly convex objective functions. In addition, the introduction of momentum in NAG softens the dependence of convergence rate on the condition number of the problem. Since high dimensional problems often correspond to larger condition numbers, it is conventional wisdom that adding momentum to gradient descent makes it scale better with high dimensional problems (e.g., Ruder (2016), and Cheng et al. (2018) for rigorous results on related problems).

In particular, at least two versions of NAG have been widely used, referred to as NAG-SC and NAG-C for instance in Shi et al. (2018). While their original versions are iterative methods in discrete time, their continuum limits (as the step size goes to zero) have also been studied: for example, Su et al. (2014) thoroughly investigates these limits as ODEs, and Wibisono et al. (2016) establishes a corresponding variational principle (along with other generalizations). Further developments exist; for instance, Shi et al. (2018) discusses how to better approximate the original NAGs by high-resolution NAG-ODEs when step size is small but not infinitesimal, and was followed up by Wang and Tao (2020). Note, however, that no variational principle has been provided yet for the high-resolution NAG-ODEs, to the best of our knowledge.

Although the aforementioned discussions on NAG are in the context of finite dimensional vector space, a variational principle can allow it to be intrinsically generalized to manifolds. Such generalizations are meaningful, because objective functions may not always be a function on vector space, and abundant applications require optimization with respect to parameters in curved spaces. The first part of this article generalizes continuous NAG dynamics to Lie groups, which are differentiable manifolds that are also groups. Special orthogonal group $SO(n)$, which contains $n$-by-$n$ real orthogonal matrices with determinant 1, is a classical Lie group, and its optimization is not only relevant to data sciences (see e.g., Sec.3 and Appendix) but also to physical sciences. Some more examples include sym-
Variational Optimization on Lie Groups, with Examples of Leading (Generalized) Eigenvalue Problems

plectic groups, spin groups, and unitary groups, all of which play important roles in contemporary physics (e.g., Sattinger and Weaver (2013)); for instance, optimization on unitary groups found applications in quantum control (e.g., Glaser et al. (1998)), quantum information (e.g., Kitaev and Watrous (2000)), MIMO communication systems (e.g., Abrudan et al. (2009)), and NMR spectroscopy (e.g., Sorensen (1989)).

Variational principles on Lie groups (or more precisely, on the tangent bundle of Lie groups, for introducing velocity) provide a Lagrangian point of view for mechanical systems on Lie groups, and have been extensively studied in geometric mechanics (e.g., Marsden and Ratiu (2013); Holm et al. (2009)). Nevertheless, the application of geometric mechanics to NAG-type optimization in this article is new. The second part of this article will discretize the resulting NAG-dynamics on Lie groups, which lead to actual optimization algorithms. These algorithms are also new, although they can certainly be embedded as part of the profound existing field of geometric numerical integration (e.g., the classic monograph of Hairer et al. (2006)).

It is also important to mention that optimization on manifolds is already a field so rich that only an incomplete list of references can be provided, e.g., Gabay (1982); Smith (1994); Edelman et al. (1998); Absil et al. (2009); Patterson and Teh (2013); Zhang and Sra (2016); Zhang et al. (2016); Liu et al. (2017); Boumal et al. (2018); Ma et al. (2019); Zhang and Sra (2018); Liu et al. (2018). However, a specialization in Lie group will still be helpful, because the additional group structure (joined efforts with NAG) improves the optimization; for instance, a well known reduction is to, under symmetry, pull the velocity at any location on the Lie group back the tangent space at the identity (known as the Lie algebra).

We also note that NAG (either in vector space or on Lie group) is not restricted to convex optimization. In fact, the proposed methods will be demonstrated on an example of (leading) Generalized EigenValues (GEV) problems, which is known to be nonconvex (e.g., Chi et al. (2019) and its references therein).

GEV is a classical linear algebra problem behind tasks including Linear Discriminant Analysis (see Sec.4.3 and Appendix) and Canonical Correlation Analysis (e.g., Barnett and Preisendorfer (1987)). Due to its importance, numerous GEV algorithms exist (see e.g., Saad (2011)), some iterative (e.g., variants of power method) and some direct (e.g., Lanczos-based methods). And we choose GEV as an example to demonstrate our method applied to Lie group $SO(n)$.

Meanwhile, another line of approaches has also been popular, especially for data sciences problems, often referred to as Oja flow (Oja, 1982), Sanger’s rule (Sanger, 1989), and Generalized Hebbian Algorithm (Gorrell, 2006). While initially proposed for the leading eigenvalue problem, they extend to the leading GEV problem (e.g., Chen et al. (2019)). For a simple notation, we follow Chen et al. (2019) and denote them by ‘GHA’. GHA is based on a matrix-valued ODE, whose long time solution converges to a solution of GEV; more details are reviewed in Appendix.

Since the GHA ODE has to be discretized and numerically solved, GHA in practice is still an iterative method, but it is a special one: because of its ODE nature, GHA adapts well to a stochastic generalization of GEV, in which one only has access to noisy/incomplete realizations of the actual matrix (see Sec.3.3 for more details), and hence remains popular in machine learning. The proposed methods will also be based on ODEs and suitable to stochastic problems, and thus they will be compared with GHA (Sec.4.2). Worth mentioning is, GEV is still being actively investigated; besides Chen et al. (2019), recent progress include, for instance, Ge et al. (2016); Allen-Zhu and Li (2017); Arora et al. (2017). While the main contribution of this article is the momentum-based general Lie group optimization methodology (not GEV algorithms), the derived GEV algorithms are complementary to states-of-arts, because the proposed methods are indifferent to eigengap unlike Ge et al. (2016), and no direct access or inversion of the constraining matrix as different from Allen-Zhu and Li (2017); Arora et al. (2017); however, our method can be made stochastic but not ‘doubly-stochastic’.

This article is organized as follows. Sec.2 derives the continuous Lie-group optimization dynamics based on the NAG variational principle. Sec.3.1 describes, at the continuous level, the case when the Lie group is $SO(n)$, including the (full) eigenvalue problem and the leading GEV problem; both NAG dynamics and GD (no momentum) are discussed. Sec.3.2 then describes discretized algorithms, and Sec.3.3 extends them to stochastic problems. Sec.4 provides numerical evidence of the efficacy of our methods, with demonstrations on both synthetic and real data.

Quick user guide: For GEV, a family of NAG dynamics were obtained. The simplest ones are

\begin{align}
\text{Lie-GD:} & \quad \dot{R} = R ([R^T AR, E]) \tag{1} \\
\text{Initial condition has to satisfy:} & \quad R(0)^T BR(0) = I. \\
\text{Lie-NAG:} & \quad \dot{R} = R\xi, \quad \dot{\xi} = -\gamma(t)\xi + [R^T AR, E] \tag{2} \\
\text{where} & \quad E := \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} \text{ } n \times n. \\
\text{Initial conditions have to satisfy:} & \quad R(0)^T BR(0) = I \text{ and } \xi(0)^T = -\xi(0). \end{align}

Constant $\gamma$ and $\gamma(t) = 3/t$ respectively correspond to Lie-NAG-SC and Lie-NAG-C. If it is affordable to tune
the constant $\gamma$ value, our general recommendation is Lie-NAG-SC. Its associated optimization algorithm is Algm.2, and Algm.1 is also provided for Lie-GD.

2 Variational Optimization on Lie Group: the General Theory

2.1 Gradient Flow

Our focus is optimization problems on Lie groups: Let $G$ be a compact Lie group, $f : G \to \mathbb{R}$ be a smooth function, and consider the optimization problem

$$\min_{g \in G} f(g).$$

We may define the gradient flow for this problem as follows: Let $TG$ and $T^*G$ be the tangent and cotangent bundles of $G$, $g \in G$ be the identity, and $g := T_eG$ be the Lie algebra of $G$. Suppose that $g$ is equipped with an inner product $\langle \xi, \eta \rangle := (\xi, \eta)$ with an isomorphism $\mathbb{I} : g \to g^* : \xi \mapsto \mathbb{I}(\xi)$ where $g^*$ is the dual of the Lie algebra $g$, and $\langle \cdot, \cdot \rangle$ stands for the natural dual pairing. One can naturally extend this metric to a left-invariant metric on $G$ by defining, $\forall g \in G$ and $\forall v, w \in T_gG$, $\langle v, w \rangle := \langle T_gL_g^{-1}(v), T_gL_g^{-1}(w) \rangle$, where $L_g : G \to G : h \mapsto gh$ is the left translation by $g \in G$ and $T_hL_g : T_hG \to T_{gh}G$ is its tangent map.

Now, we define the gradient vector field $f$ on $G$ as follows: For any $g \in G$ and any $\dot{g} \in T_gG$,

$$\langle (\nabla f)(g), \dot{g} \rangle = (df)(g, \dot{g}) \quad \forall g \in G \quad \forall \dot{g} \in T_gG,$$

where $d$ stands for the exterior differential. This gives

$$(\nabla f)(g) = T_cL_g \circ \Gamma^{-1} \circ T_c^*L_g(df(g)),$$

where $T_c^*L_g$ is the dual of $T_cL_g$, i.e., $\forall \alpha \in T_g^*G$ and $\forall \xi \in g$, $(T_c^*L_g(\alpha), \xi) = (\alpha, T_cL_g(\xi))$. Hence the gradient descent equation is given by

$$\dot{g} = -(\nabla f)(g) = -T_cL_g \circ \Pi^{-1} \circ T_c^*L_g(df(g)). \quad (3)$$

2.2 Adding Momentum: the Variational Optimization

Our work provides a natural extension of variational optimization of Wibisono et al. (2016) to Lie groups making use of the geometric formulation of the Euler–Lagrange equation on Lie groups. Specifically, let us define the Lagrangian $L : TG \times \mathbb{R} \to \mathbb{R}$ as follows:

$$L(g, \xi, t) := r(t)\left(\frac{1}{2}\langle \xi, \dot{\xi} \rangle - f(g)\right), \quad (4)$$

where $r : \mathbb{R} \to \mathbb{R}_{> 0}$ is a smooth positive-valued function. Instead of working with the tangent bundle $TG$ directly, it is more convenient to use the left-trivialization of $TG$, i.e., we may identify $TG$ with $G \times g$ via the map $G \times g \to TG ; (g, \xi) \mapsto (g, T_gL_g(\xi))$. Under this identification, we have the Lagrangian $L : G \times g \times \mathbb{R} \to \mathbb{R}$ defined as

$$L(g, \xi, t) := r(t)\left(\frac{1}{2}\langle \xi, \xi \rangle - f(g)\right). \quad (5)$$

The Euler–Lagrange equation for this Lagrangian is (see, e.g., Holm et al. (2009, Section 7.3) and also Marsden and Ratiu (2013))

$$\frac{d}{dt} \left(\frac{\delta L}{\delta \xi}\right) = ad^*_\xi \frac{\delta L}{\delta \xi} + T^*_cL_g(df_L),$$

along with

$$\dot{\xi} = T_cL_g(\xi) = : g\xi, \quad (6)$$

where $ad^*$ is the coadjoint operator; $\delta L/\delta \xi \in g^*$ is defined so that, for any $\delta \xi \in g$,

$$\left(\frac{\delta L}{\delta \xi}, \delta \xi \right) = \frac{d}{ds} L(g, \xi + s\delta \xi, t) \bigg|_{s=0};$$

also note that $d_LL$ stands for the exterior differential of $\xi \mapsto L(g, \xi, t)$. Using the above expression (5) of the Lagrangian, we obtain

$$\frac{d}{dt} \mathbb{I}(\xi) = -\gamma(t)\mathbb{I}(\xi) + ad^*_\xi \mathbb{I}(\xi) - T^*_cL_g(df_L), \quad (7)$$

where we defined $\gamma(t) := r'(t)/r(t)$.

**Choices of $\gamma$.** We will mainly consider $\gamma(t) = \gamma$ (constant) and $\gamma(t) = 3/t$, derived from $r = \exp(\gamma t)$ and $r = t^3$. In vector space, these two choices respectively correspond to, as termed for instance in Shi et al. (2018), NAG-SC and NAG-C, which are the continuum limits of two classical versions of Nesterov’s Accelerated Gradient methods (Nesterov, 1983, 2018).

**Lyapunov function.** Let $t \mapsto (g(t), \xi(t))$ be a solution of eq. (7). Assuming that $g_0$ is an isolated local minimum of $f$, we can show that the dynamics starting in a neighborhood of $g_0$ converges to $g_0$ as follows. Define the “energy” function $E : G \times g \to \mathbb{R}$ as

$$E(g, \xi) := \frac{1}{2}\langle \xi, \xi \rangle + f(g) = \frac{1}{2}\langle \mathbb{I}(\xi), \xi \rangle + f(g). \quad (8)$$

This gives a Lyapunov function. In fact, there exists a neighborhood $U$ of $(g_0, 0)$ such that $E(g, \xi) \geq f(g)$ for any $(g, \xi) \in U \setminus \{(g_0, 0)\}$. Moreover, we have $\frac{d}{dt} E(g(t), \xi(t)) = -\gamma(\langle \xi, \xi \rangle \leq 0$, where the equality implies $\xi = 0$, for which (7) gives $df_L = 0$, which locally gives $g = g_0$. 
3 The Example of SO(\(n\)) and Its Application to Leading GEV

3.1 The Continuous Formulations

3.1.1 The Symmetric Eigenvalue Problem

Let \(A\) be a real symmetric \(n \times n\) matrix, and define, as in Brockett (1990); Mahony and Manton (2002),
\[
f : SO(n) \to \mathbb{R}; 
\]
where \(N := \text{diag}(1, 2, \ldots, n)\). We equip the Lie algebra \(so(n)\) with the inner product \(\langle \xi, \eta \rangle := \text{tr}(\xi^T \eta)\). Then we may identify \(so(n)^*\) with \(so(n)\) via this inner product. Then the “force” term in (7) is given by
\[
T^\dagger L_R(df(R)) = [R^T A R, N].
\]
Since \(\text{ad}^\xi \mu = [\mu, \xi]\) for any \(\xi \in so(n)\) and \(\mu \in so(n)^* \cong so(n)\), (7) becomes
\[
\dot{R} = R\xi, \quad \dot{\xi} = -\gamma \xi + I^{-1}(\|\xi\|^2 - [R^T A R, N]),
\]
whereas the gradient descent equation (3) gives
\[
\dot{R} = -RI^{-1}([R^T A R, N]).
\]

Remark 3.1 (Rigorous results v.s. intuitive addition of momentum). The above dynamics work for any positive definite isomorphism \(\mathbb{R} \to g^*\). For simplicity, we will use \(\mathbb{I} = \text{id}\) (where \(g^*\) is identified with \(g\)) in implementations in this article. In this case, the \(\|\xi\|, \dot{\xi}\) term and the \(I^{-1}\) operation vanish, and the momentum version (9) is heuristically obtainable from (10) just like how momentum was added to gradient flow in vector spaces. Otherwise, they create additional nontrivial nonlinearities that account for the curved space.

Remark 3.2 (Relation to double-bracket). When \(\mathbb{I} = \text{id}\), the gradient flow (10) becomes \(\dot{R} = -R([R^T A R, N])\). By setting \(M(t) := R(t)^T A R(t)\), we recover the double-bracket equation \(\dot{M} = -[M, [M, N]]\) of Brockett (1991) (see also Bloch et al. (1992)). Note that there is a sign difference from Brockett (1991) because Brockett’s is gradient ascent.

Remark 3.3 (Generality). The proposed methods, Lie-NAG (9) and Lie-GD (10), are indifferent to the absolute location of \(A\)’s eigenvalues, because they are invariant to the shift \(A \mapsto A + \lambda I\). To see this, note
\[
[R^T A R, N] \mapsto [R^T (A + \lambda I) R, N] = [R^T A R, N] + \lambda [R^T R, N] = [R^T A R, N] + \lambda [I, N] = [R^T A R, N].
\]
Therefore, the proposed methods work the same no matter whether \(A\) is positive/negative-definite. In the generalized eigenvalue setting (see future Sec.3.1.3), the same reasoning and invariance hold for \(L^{-T} A L^{-1} \mapsto L^{-T} A L^{-1} + \lambda I\) where \(L^T L = B\).

3.1.2 The Leading \(l\) Eigenvalue Problem

Let \(A\) be a real symmetric \(n \times n\) matrix. Since finding the smallest \(l\) eigenvalues of \(A\) is the same as finding the largest \(l\) eigenvalues of \(-A\), define
\[
f : SO(n) \to \mathbb{R}; 
\]
where \(E := [I_l]\) is \(n \times l\) where \(I_l\) is the \(l \times l\) identity matrix and 0 is the \((n - l) \times l\) zero matrix. The cost function is almost the same as the previous case except that \(N\) is now replaced by
\[
\mathcal{E} := EE^T = [I_l^T 0].
\]
So we have \(T^\dagger L_R(df(R)) = -[R^T A R, \mathcal{E}]\).

3.1.3 The Leading \(l\) Generalized Eigenvalues

Consider the leading \(l\) Generalized EigenValues problem (GEV): given \(n\)-by-\(n\) symmetric \(A\) and \(n\)-by-\(n\) positive definite \(B\), we seek an optimizer of
\[
\max_{V \in \mathbb{R}^{n \times 1}} \text{tr}(V^T A V) \quad \text{s.t.} \quad V^T B V = I_{l \times l}. \tag{12}
\]
It can be seen, by Cholesky decomposition \(B = L^T L\) and a Lie group isomorphism \(X \mapsto LX\), that \(\mathbb{R}^{n \times 1} \to \mathbb{R}^{n \times l}\).

Proposition 3.1. \(G = \{X | X \in \mathbb{R}^{n \times n}, X^T BX = I\} \) is a Lie group. Its identity is \(L^{-1}\), and its multiplication is not the usual matrix multiplication but \(X_1 \cdot X_2 = X_1 LX_2\).

Therefore, in theory, GEV can be solved by padding \(V\) into \(X\) and then following our general approach (7). The point of this section is to make this solution explicit, and more importantly, to show \(L\) is never explicitly needed, which leads to computational efficiency. In fact, the same NAG dynamics
\[
\dot{R} = R\xi, \quad \dot{\xi} = -\gamma(t)\xi + [R^T A R, \mathcal{E}] \tag{13}
\]
with initial conditions satisfying
\[
R(0)^T B R(0) = I, \quad \xi(0)^T = -\xi(0)
\]
will solve (12) upon projecting the first \(l\) columns of \(R\) into \(V\).

Note the only difference from the previous two sections is the initial condition on \(R\). In addition, although positive definite \(B\) is needed for the group isomorphism, it is only a sufficient (not necessary) condition for NAG (13) to work.

A rigorous justification of why (13) works for not only EV but also GEV can be found in Appendix, where one will also find the proof of a quick sanity check:

Theorem 3.1. Under (13) and consistent initial condition, \(R(t)^T B R(t) = I\) and \(\xi(t)^T = -\xi(t)\) for all \(t\).
The objective function itself does not decrease monotonically in NAG, because it acts as potential energy, which exchanges with kinetic energy, but the total energy decreases (eq.8).

On the other hand, if one considers Lie-GD, which can be shown to generalize to GEV also by only modifying the initial condition (given by (1)), then not only does \( R(t) \) stay on the Lie group \( G \) (see Appendix), but also is the objective function \( \text{tr}[-(R^T(t)AR(t)E)] \) monotone (by construction).

3.2 The Discrete Algorithms

Define Cayley transformation\(^1\) as \( \text{Cayley}(\xi) := (I - \xi/2)^{-1}(I + \xi/2) \). It will be useful as a 2nd-order structure-preserving approximation of matrix \( \exp \), the latter of which is computationally too expensive. More precisely, \( \exp(h\xi) = \text{Cayley}(h\xi) + \mathcal{O}(h^3) \).

**Lie-GD.** We adopt a 1st-order (in \( h \)) explicit discretization of the dynamics \( \dot{R} = R(\dot{R}^T AR, E) \):

**Algorithm 1** A 1st-order Lie-GD for leading GEV

1: \( \text{Initialize with some } R_0 \text{ satisfying } R_0^T BR_0 = I \).
2: for \( i = 0, \ldots, \text{TotalSteps-1} \) do
3: \( f_i \leftarrow R_i^T AR_i E - E R_i^T AR_i \).
4: \( R_{i+1} \leftarrow R_i \text{Cayley}(h f_i) \).
5: end for
6: Output \( R_{\text{TotalSteps}} \) as argmin \( f \) in (11).

Note Algm.1 is more accurate than forward Euler discretization despite that both are 1st-order. This is because all \( R_i \)'s it produces will remain on the Lie group (i.e., \( R_i^T BR_i = I \); see Thm.4.2 in Appendix).

**Lie-NAG.** We present a 2nd-order (in \( h \)) explicit discretization of the dynamics \( \dot{R} = R \xi, \dot{\xi} = -\gamma(t)\xi + [\dot{R}^T AR, E] \). Unlike the Lie-GD case, the discretization was achieved by the powerful machinery of operator splitting, and can be easily generalized to arbitrarily high-order (e.g., McLachlan and Quispel (2002); Tao (2016)), provided that Cayley transformation was replaced by a higher-order Lie-group-preserving approximation of matrix exponential.

More precisely, denote by \( \phi^h \) the exact \( h \)-time flow of the NAG dynamics, and by \( \phi_1^h \) and \( \phi_2^h \) some \( p \)-th order approximations of the \( h \)-time flows of \( \dot{R} = R \xi, \dot{\xi} = 0 \) and \( \dot{R} = 0, \dot{\xi} = -\gamma(t)\xi + [\dot{R}^T AR, E] \). Note even though \( \phi \) is unavailable, the latter systems are analytically solvable, so if \( \exp(h\xi) \) is exactly computed, \( \phi_1 \) and \( \phi_2 \) can be made exact. Even if they are just \( p \)-th order approximations (\( p \geq 2 \)), operator splitting yields \( \phi^h = \phi_2^h \circ \phi_1^h \circ \phi_2^{h/2} + \mathcal{O}(h^3) \). Other ways of composing \( \phi_1, \phi_2 \) can lead to higher order methods (Appendix describes some 4th-order options), with maximum order capped by \( p \). For simpler coding, \( \xi = -\gamma(t)\xi + [\dot{R}^T AR, E] \) can be further split into \( \xi = -\gamma(t)\xi \) and \( \xi = [\dot{R}^T AR, E] \), and Algm.2 is based on \( \phi_3^{h/2} \circ \phi_2^{h/2} \circ \phi_1^{h/2} \circ \phi_3^{h/2} \).

**Algorithm 2** A 2nd-order Lie-NAG for leading GEV

1: \( \text{Initialize with some } R_0 \text{ satisfying } R_0^T BR_0 = I \) and \( \xi_0^2 = -\xi_0 \).
2: for \( i = 0, \ldots, \text{TotalSteps-1} \) do
3: \( \xi_i \leftarrow \xi_i + h/2(\dot{R}_i^T AR_i E - E \dot{R}_i^T AR_i) \).
4: \( \xi_i \leftarrow \left\{ \begin{array}{ll} \exp(-\gamma h/2)\xi_i, & \text{for NAG-SC} \\ (((ih)^3/(i + 1/2)h^3))\xi_i, & \text{for NAG-C} \end{array} \right. \)
5: \( R_{i+1} \leftarrow R_i \text{Cayley}(h\xi_i) \).
6: \( \xi_{i+1} \leftarrow \left\{ \begin{array}{ll} \exp(-\gamma h/2)\xi_{i+1}, & \text{NAG-SC} \\ (((i + 1/2)h^3)/(i + 1)h^3)\xi_{i+1}, & \text{NAG-C} \end{array} \right. \)
7: \( \xi_{i+1} \leftarrow \xi_{i+1} + h/2(\dot{R}_{i+1}^T AR_{i+1} E - E \dot{R}_{i+1}^T AR_{i+1}) \).
8: end for
9: Output \( R_{\text{TotalSteps}} \) as argmin \( f \) in (11).

Also by Thm.4.2, all \( R_i \)'s remain on the Lie group if arithmetics have infinite machine precision.

In addition, Algm.2 is conformal symplectic (see Appendix), which is indicative of favorable accuracy in long time energy behavior. To prove so, note both \( \phi_1 \) and \( \phi_3 \) as exact Hamiltonian flows preserve the canonical symplectic form, and two substeps of \( \phi_2 \) as linear maps discount it by a multiplicative factor of \( r(t_i)/r(t_{i+1}) \). This exactly agrees with the continuous theory in Appendix.

3.3 Generalization to Stochastic Problems

**Setup:** now let us consider a Stochastic Gradient (SG) setup, where one may not have full access to \( A \) but only a finite collection of its noisy realizations. More precisely, given one realization of i.i.d. random matrices \( A_1, \ldots, A_K \), the goal is to compute the leading (generalized) eigenvalues of \( A = \frac{1}{K} \sum_{k=1}^{K} A_k \) based on \( A_k \)'s without explicitly using \( A \).

**Implementation:** following the classical stochastic gradient approach, we simply replace \( A \) in each algorithm by \( A_k \), where \( \kappa \) is a uniform random variable on \([K]\), independently drawn at each timestep.

**Remark 3.4.** Like Ge et al. (2016) and unlike Chen et al. (2019), the proposed methods do not allow \( B \) to be a stochastic approximation. Only \( A \) can be stochastic. On the other hand, unlike both Ge et al. (2016) and Chen et al. (2019), we do not require a direct access to \( B \), and all information about \( B \) is reflected in the initial condition \( R(0) \).

**Intuition:** we now make heuristic arguments to gain insights about the performance of the method.
First, based on the common approximation of stochastic gradient as batch gradient plus Gaussian noise (see e.g., Li et al. (2019) for some state-of-art quantifications of the accuracy of this approximation), assume $A_\kappa = A + \sigma H$ where $H$ is a symmetric Gaussian matrix (assumed as $H = \Xi + \Xi^T$ where $\Xi$ is an $n$-by-$n$ matrix with i.i.d. standard normal elements), i.i.d. at each step. Then the gradient $[R^T A_\kappa R, \mathcal{E}]$ is, in distribution and conditioned on $R$, equal to $[R^T A R, \mathcal{E}] + 2\sigma E$. This is because $[R^T A_\kappa R, \mathcal{E}]$ is Gaussian and its mean is $[R^T A R, \mathcal{E}]$ and covariance is $\sigma^2\text{covar}[[R^T H R, \mathcal{E}]][R]$, which can be computed to be $4\sigma^2I$, independent of $R$ as long as $R^T R = I$ and $\mathcal{E}$ is a degenerate identity. Therefore, at least in the case of $I = \text{id}$, the Lie-NAG SG dynamics can be understood through

$$\dot{R} = R\xi, \quad \dot{\xi} = -\gamma(t)\xi + [R^T A R, \mathcal{E}] + 2\sigma E,$$  \hspace{1cm} (14)

where $E$ is a skew-symmetric white-noise, i.e., $E_{ij}$ with $i < j$ being i.i.d. white noise, $E_{ji} = -E_{ij}$, and $E_{ii} = 0$, and $\sigma = \sigma$ in this continuous setting.

Worth mentioning is, once one uses a numerical discretization, namely

$$\xi_{t+1} = \xi_t - h\gamma(t)\xi_t + h[R^T A_t R_t, \mathcal{E}] + o(h),$$

$$\dot{\xi_t} = -h\gamma(t)\xi_t + [R^T A_t R_t, \mathcal{E}] + h2\sigma E_t + o(h)$$

then since $\kappa$ does not randomize infinitely frequently, the effective noise amplitude $\tilde{\sigma}$ gets scaled as

$$\tilde{\sigma} = \sqrt{h}\sigma + o(\sqrt{h}),$$  \hspace{1cm} (15)

because a 1st-order discretization of (14) should have its $\xi$ component being

$$\xi_{t+1} = \xi_t - h\gamma(t)\xi_t + h[R^T A R_t, \mathcal{E}] + \sqrt{2}\tilde{\sigma} E_t + o(h)$$

due to stochastic calculus. This leads to $h2\sigma E_t = \sqrt{2}\tilde{\sigma} E_t + o(h)$, and hence (15).

Secondly, recall an analogous vector space setting, in which one considers

$$\dot{q} = p, \quad \dot{p} = -\gamma p - \nabla V(q) + \tilde{\sigma} e$$

where $e$ is standard vectorial white-noise. It is well known that under reasonable assumptions (e.g., Pavliotis (2014)) this diffusion process admits, and converges weakly to an invariant distribution of $Z^{-1}\exp(-H(q, p)/kT) dq dp$, where $H = ||p||^2/2 + V(q)$ is the Hamiltonian, $Z$ is some normalization constant, and $kT = \sigma^2/(2\gamma)$ is the temperature (with unit).

It is easy to see that for the purpose of optimization, the temperature should be small. If one uses vanishing stepsizes, since $\tilde{\sigma}^2 = h\sigma^2$, $kT \to 0$, and stochastic optimization can be guaranteed to work (more details in Robbins and Monro (1951)). If $h$ is small but not infinitesimal, $q$ (or $R$) is still concentrated near the optimum value(s) with high probability.

Now recall Lie-NAG-SC uses constant $\gamma$; Lie-NAG-C, on the contrary, uses $\gamma(t) = 3/t$. This means Lie-NAG-SC equipped with SG converges to some invariant distribution at temperature $h\sigma^2/(2\gamma)$, but Lie-NAG-C's `temperature' $kT = h\sigma^2/(6/t)$ grows unbounded with $t$ for constant $h$; i.e., constant stepsizes Lie-NAG-C-SG doesn't converge even in a weak sense.

This is another reason that our general recommendation is Lie-NAG-SC over Lie-NAG-C. On the other hand, there are multiple possibilities to correct the non-convergence of Lie-NAG-C: (i) appropriately vanishing $h$ can lead to recovery of an invariant distribution, but to obtain a fixed accuracy one would need more steps; (ii) one can add a correction to the dynamics (Wang and Tao, 2020); (iii) modify $\gamma(t)$.

**Corrected dissipation coefficient:** this article experimented with option (iii) with

$$\gamma = 3/t + ct, \quad \text{where } c \text{ is a small constant};$$  \hspace{1cm} (16)

see Sec.4.2. This choice corresponds to $r(t) = \exp(ct^2/2)^{1/3}$ in the variational formulation. Formally, it leads to 0 temperature, but in practice early stopping is needed because any finite $h$ cannot properly numerical-integrate the dynamics when $\gamma$ becomes sufficiently large.

The reason for choosing the specific linear form of the correction $+ct$ is in Appendix.

### 4 Experiments

#### 4.1 Leading Eigenvalue Problems

##### 4.1.1 Bounded Spectrum

We first test the proposed methods on a synthetic problem: finding the $l$ largest eigenvalues of $A = (\Xi + \Xi^T)/2/\sqrt{n}$, where $\Xi$ is a sample of an $n$-by-$n$ matrix with i.i.d. standard normal elements. The scaling of $1/\sqrt{n}$ ensures the leading eigenvalues are bounded by a constant independent of $n$; for an unbounded case, see the next example.

Fig. 1 shows results for a generic sample of 500-dimensional $A$. The proposed Lie-NAG’s, i.e. variational methods with momentum, converge significantly faster than the popular GHA. This advantage is even more significant in higher dimensions (see Fig. 6 in Appendix). Note Fig. 1 plots accuracy as a function of

---

For more precise statement and justification, see random matrix theory for Gaussian Orthogonal Ensemble (GOE), or more generally Wigner matrix Wigner (1958)
Figure 1: Performances of proposed Lie-GD, Lie-NAG-C and Lie-NAG-SC, compared with GHA, for computing the leading \( l = 2 \) eigenvalues of scaled GOE. All algorithms use step sizes tuned to minimize error in \( 5 \times 10^4 \) iterations (although the proposed methods do not need much tuning), and identity initial condition. GHA was based on Runge-Kutta-4 integration of \( \dot{Q} = (I - QQ^T)AQ \) for accuracy, and an Euler integration did not result in any notable error reduction. NAG-SC uses friction coefficient untuned \( \gamma = 1 \). The deviations of Lie-NAGs and Lie-GD from the Lie group are machine/platform (MATLAB) precision artifacts.

The number of iterations, and readers interested in accuracy as a function of wallclock are referred to Fig. 7 (note wallclock count is platform dependent and therefore the latter illustration is only qualitative but not quantitative, thus placed in the Appendix). In any case, for this problem at least, if low-moderate accuracy is desired, Lie-NAG-C is the most efficient among tested methods; if high accuracy is desired instead, Lie-NAG-SC is the optimal choice.

Note the fact that \( A \) has both positive and negative eigenvalues should not impair the credibility of this demonstration. This is because one can shift \( A \) to make it positive definite or negative definite, and the convergences will be precisely the same. See Rmk.3.3.

4.1.2 Unbounded Spectrum

Now consider computing the leading eigenvalues of \( A = -\Xi\Xi^T/2 \) (\( \Xi \) similarly defined as in Sec.4.1.1). This is equivalent to finding the \( l \) smallest eigenvalues of \( \Xi\Xi^T/2 \). Doing so is relevant, for instance, in graph theory, where the 2nd smallest eigenvalue of graph Laplacian is the algebraic connectivity of the graph (Fiedler, 1973; Von Luxburg, 2007).

Fig.2 shows the advantage of variational methods (i.e., with momentum), even when the dimension is relatively low \( n = 25 \). \( A \) is defined such that its spectrum grows linearly with \( n \), and GHA thus needs to use tiny timesteps. Although the proposed methods also need to use reduced step sizes for bigger \( n \), the rate of reduction is much slower than that for GHA (results omitted).

4.2 Stochastic Leading Eigenvalue Problems

To investigate the efficacy of the proposed methods in the stochastic setup (Sec.3.3), we take the same \( A \) from Sec.4.1.1, and add \( K = 100 \) random perturbations to it to form a batch \( A_1, \ldots, A_K \). Each random perturbation is \( (\Xi + \Xi^T)/4\sqrt{n} \) for i.i.d. \( \Xi \); note these are large fluctuations when compared to \( A \). Then \( A \) is refreshed to be the mean of \( A_k \)’s, whose leading \( l = 2 \) eigenvalues are accurately computed as the ground truth.

Fig.3 shows the advantage of variational methods, even though their larger step sizes lead to much higher variances of the stochastic gradient approximation. The corrected dissipation (16) enabled the convergence of NAG-C. The same correction slows down the convergence of NAG-SC in the beginning, but significantly improves its long time performance, which otherwise stagnates at small but not infinitesimal error.

The reason NAG-SC-original stagnates is, over long time, it samples from an invariant distribution at a nonzero temperature. This invariant distribution, however, is not the exact one of the continuous limit; the latter of which would concentrate around the minimizer with 0 error. Instead, the numerical method’s invariant distribution, if existent, is \( O(h^p) \) away from the exact one (Bou-Rabee and Owhadi, 2010; Abdulle...
Variational Optimization on Lie Groups, with Examples of Leading (Generalized) Eigenvalue Problems

Figure 3: The computation of leading $l = 2$ eigenvalues of $A = \frac{1}{K} \sum_{k=1}^{K} A_k$ based on stochastic gradients from batch $A_1, \ldots, A_K$ without $A$. NAG-SC corrected, NAG-C corrected, NAG-SC and NAG-C use, respectively, $\gamma = 1 + 0.01t$, $3/t + 0.01t$, 1, and $3/t$. Other descriptions are same as in Fig.1.

et al., 2014) under suitable assumptions, which means as the numerical method converges, it gives $R$’s that are $O(h^p)$ away from the exact minimizer with high probability. NAG-SC-corrected alleviated this issue.

4.3 Leading Generalized Eigenvalue: a Demonstration Based on LDA

We report numerical experiments on multiclass Fisher Linear Discriminant Analysis (LDA) of the handwritten-digits database MNIST (LeCun et al., 1998). Since it is known that LDA can be formulated as a leading generalized eigenvalue problem (e.g., reviewed in Li et al. (2006); Welling (2005); see appendix for a summary), we use it as an example to test our leading GEV algorithm. Important to note is, our purpose is NOT to construct an algorithm for MNIST classification, as it is known that LDA does not achieve state-of-art performance in that regard (test error based on exact leading GEV solution was 10% in our experiment). Instead, we simply would like to quantify the efficacy of our algorithm applied to a leading generalized eigenvalue problem based on real life data.

The 60000 training data of MNIST were employed to compute the ‘inter-class scatter matrix’ $A$ and the ‘intra-class scatter matrix’ $B$ (see appendix for more details). Each $28 \times 28$ image had its white margins cropped, resulting in a 400-dimensional vector, and thus $A$ and $B$ are both 400-by-400, respectively positive semi-definite and positive definite. Furthermore, to avoid laborious tuning of timestep sizes, both $A$ and $B$ are normalized by their respective 2-norm; this is without loss of generality, because arg min$_Q \det(Q^T A Q)/\det(Q^T B Q)$ is invariant to scaling of $A$ and/or $B$. Since there are 10 classes, $l = 9$ is chosen.

Note this is a positive semi-definite problem by construction. Some generalized eigenvalue methods require or prefer such a property (e.g., Oja flow (Yan et al., 1994)), but the proposed algorithms are indifferent to the definiteness (see Rmk.3.3).

Figure 4: Lie-GD, Lie-NAG-C, Lie-NAG-SC, and GHA, for computing the leading $l$ generalized eigenvalues associated with LDA for the MNIST dataset. All algorithms use step sizes tuned to minimize error in $10^4$ iterations (although the proposed methods do not need much tuning). Two GHA runs use two initial conditions, $Q(0) = I$ which is not on the Lie group $Q^T B Q = I$, and $Q(0)$ being the first $l$ columns of $L^{-1}$ which is on the Lie group; all others use initial condition $L^{-1}$. GHA was based on Runge-Kutta-4 integration of $\dot{Q} = (I - BQQ^T)AQ$ for accuracy, and an Euler integration did not result in any notable error reduction. NAG-SC uses friction coefficient untuned $\gamma = 1$. The pollution of NAG simulations near the end is a machine precision artifact, and so are the deviations of Lie-NAGs and Lie-GD from the Lie group.

Fig.4 shows that all proposed methods converge significantly faster than GHA. Interestingly, although Lie-NAG-SC still converges faster than Lie-GD, the acceleration due to momentum is not as drastic as before.

In addition, Fig.5 in Appendix shows that our methods do not require an eigengap, and thus are widely applicable. Great methods have been continuously proposed for GEV; for instance, a globally linear convergent algorithm was recently proposed based on power method (Ge et al., 2016), but its convergence is affected by eigengap. The proposed methods do not have this restriction.
