On the Convergence of Nesterov’s Accelerated Gradient Method in Stochastic Settings

Mahmoud Assran\textsuperscript{1,2,3} Michael Rabbat\textsuperscript{2,3}

Abstract

We study Nesterov’s accelerated gradient method with constant step-size and momentum parameters in the stochastic approximation setting (unbiased gradients with bounded variance) and the finite-sum setting (where randomness is due to sampling mini-batches). To build better insight into the behavior of Nesterov’s method in stochastic settings, we focus throughout on objectives that are smooth, strongly-convex, and twice continuously differentiable. In the stochastic approximation setting, Nesterov’s method converges to a neighborhood of the optimal point at the same accelerated rate as in the deterministic setting. Perhaps surprisingly, in the finite-sum setting, we prove that Nesterov’s method may diverge with the usual choice of step-size and momentum parameters in the stochastic approximation setting (unless additional conditions on the problem related to conditioning and data coherence are satisfied). Our results shed light as to why Nesterov’s method may fail to converge or achieve acceleration in the finite-sum setting.

1. Introduction

First-order stochastic methods have become the workhorse of machine learning, where many tasks can be cast as optimization problems,

\[
\min_{x \in \mathbb{R}^d} f(x).
\]  

However, the theoretical understanding of accelerated methods remains limited when used with stochastic gradients.

This paper studies the accelerated gradient (AG) method of Nesterov (1983) with constant step-size and momentum parameters. Given an initial point \(x_0\), and with \(x_{-1} = x_0\), the AG method repeats, for \(k \geq 0\),

\[
y_{k+1} = x_k + \beta(x_k - x_{k-1})
\]

\[
x_{k+1} = y_{k+1} - \alpha g_{k+1},
\]

where \(\alpha\) and \(\beta\) are the step-size and momentum parameters, respectively, and in the deterministic setting, \(g_{k+1} = \nabla f(y_{k+1})\). When the momentum parameter \(\beta = 0\), AG simplifies to standard gradient descent (GD). When \(\beta > 0\) it is possible to achieve accelerated rates of convergence for certain combinations of \(\alpha\) and \(\beta\) in the deterministic setting.

1.1. Previous Work with Deterministic Gradients

Suppose that the objective function in (1) is \(L\)-smooth and \(\mu\)-strongly-convex. Then \(f\) is minimized at a unique point \(x^*\), and we denote its minimum by \(f^* = f(x^*)\). Let \(Q := L/\mu\) denote the condition number of \(f\). In the deterministic setting, where \(g_k = \nabla f(y_k)\) for all \(k\), GD with constant step-size \(\alpha = 2/(L+\mu)\) converges at the rate (Polyak, 1987)

\[
f(x_k) - f^* \leq \frac{L}{2} \left( \frac{Q - 1}{Q + 1} \right)^{2k} \|x_0 - x^*\|^2.
\]  

The AG method with constant step-size \(\alpha = 1/L\) and momentum parameter \(\beta = \frac{\sqrt{Q} - 1}{\sqrt{Q} + 1}\) converges at the rate (Nesterov, 2004)

\[
f(x_k) - f^* \leq L \left( \frac{\sqrt{Q} - 1}{\sqrt{Q}} \right)^k \|x_0 - x^*\|^2.
\]

The rate in (5) (up to constants) the tightest-known worst-case lower bound achievable by any first-order black-box method for \(\mu\)-strongly-convex and \(L\)-smooth objectives:

\[
f(x_k) - f^* \geq \frac{\mu}{2} \left( \frac{\sqrt{Q} - 1}{\sqrt{Q} + 1} \right)^{2k} \|x_0 - x^*\|^2.
\]  

The lower bound (6) is proved in Nesterov (2004) in the infinite dimensional setting under the assumption \(Q > 1\).
Accordingly, Nesterov’s Accelerated Gradient method is considered optimal in the sense that the convergence rate in (5) depends on \(\sqrt{Q}\) rather than \(Q\).

The proof of (5) presented in Nesterov (2004) uses the method of estimate sequences. Several works have set out to develop better intuition for how the AG method achieves acceleration though other analysis techniques.

One line of work considers the limit of infinitesimally small step-sizes, obtaining ordinary differential equations (ODEs) that model the trajectory of the AG method (Su et al., 2014; Defazio, 2019; Laborde & Oberman, 2019). Allen-Zhu & Orecchia (2014) view the AG method as an alternating iteration between mirror descent and gradient descent and show sublinear convergence of the AG method for smooth convex objectives.

Lessard et al. (2016) and Hu & Lessard (2017) frame the AG method and other popular first-order optimization methods as linear dynamical systems with feedback and characterize their convergence rate using a control-theoretic stability framework. The framework leads to closed-form rates of convergence for strongly-convex quadratic functions with deterministic gradients. For more general (non-quadratic) deterministic problems, the framework provides a means to numerically certify rates of convergence.

1.2. Previous Work with Stochastic Gradients

When Nesterov’s method is run with stochastic gradients \(g_{k+1}\), typically satisfying \( \mathbb{E}[g_{k+1}] = \nabla f(y_{k+1}) \), we refer to it as the \textit{accelerated stochastic gradient} (ASG) method. In this setting, if \(\beta = 0\) then ASG is equivalent to \textit{stochastic gradient descent} (SGD).

Despite the widespread interest in, and use of, the ASG method, there are no definitive theoretical convergence guarantees. Wiegerinck et al. (1994) study the ASG method in an online learning setting and show that optimization can be modelled as a Markov process but do not provide convergence rates. Yang et al. (2016) study the ASG method in the smooth strongly-convex setting, and show an \(O(1/\sqrt{k})\) convergence rate when employed with a diminishing step-size and bounded gradient assumption, but the rates obtained are slower than those for SGD.

Recent work establishes convergence guarantees for the ASG method in certain restricted settings. Aybat et al. (2019) and Kulunchakov & Mairal (2019a) consider smooth strongly-convex functions in a stochastic approximation model with gradients that are unbiased and have bounded variance, and they show convergence to a neighborhood when running the method with constant step size and momentum. Can et al. (2019) further establish convergence in Wasserstein distribution under a stochastic approximation model. Laborde & Oberman (2019) study a perturbed ODE and show convergence for diminishing step-size. Vaswani et al. (2019) study the ASG method with constant step-size and diminishing momentum, and show linear convergence under a strong-growth condition, where the gradient variance vanishes at a stationary point.

Some results are available for other momentum schemes. Loizou & Richtárík (2017) study Polyak’s heavy-ball momentum method with stochastic gradients for randomized linear problems and show that it converges linearly under an exactness assumption. Gitman et al. (2019) characterize the stationary distribution of the Quasi-Hyperbolic Momentum (QHM) method (Ma & Yarats, 2019) around the minimizer for strongly-convex quadratic functions with bounded gradients and bounded gradient noise variance.

The lack of general convergence guarantees for existing momentum schemes, such as Polyak’s and Nesterov’s, have led many authors to develop alternative accelerated methods specifically for use with stochastic gradients (Lan, 2012; Ghadimi & Lan, 2012; 2013; Allen-Zhu, 2017; Kidambi et al., 2018; Cohen et al., 2018; Kulunchakov & Mairal, 2019b; Liu & Belkin, 2020).

Accelerated first-order methods are also known to be sensitive to inexact gradients when the gradient errors are deterministic (possibly adversarial) and bounded (d’Aspremont, 2008; Devolder et al., 2014).

1.3. Contributions

We provide additional insights into the behavior of Nesterov’s accelerated gradient method when run with stochastic gradients by considering two different settings. We first consider the stochastic approximation setting, where the gradients used by the method are unbiased, conditionally independent from iteration to iteration, and have bounded variance. We show that Nesterov’s method converges at an accelerated linear rate to a region of the optimal solution for smooth strongly-convex quadratic problems.

Next, we consider the finite-sum setting, where \(f(x) = \frac{1}{n} \sum_{i=1}^{n} f_i(x)\), under the assumption that each term \(f_i\) is smooth and strongly-convex, and the only randomness is due to sampling one or a mini-batch of terms at each iteration. In this setting we prove that, even when all functions \(f_i\) are quadratic, Nesterov’s ASG method with the usual choice of step-size and momentum cannot be guaranteed to converge without making additional assumptions on the condition number and data distribution. When coupled with convergence guarantees in the stochastic approximation setting, this impossibility result illuminates the dichotomy between our understanding of momentum-based methods in the stochastic approximation setting, and practical implementations of these methods in a finite-sum framework.

Our results also shed light as to why Nesterov’s method may
fail to converge or achieve acceleration in the finite-sum setting, providing further insight into what has previously been reported based on empirical observations. In particular, the bounded-variance assumption does not apply in the finite-sum setting with quadratic objectives.

We also suggest choices of the step-size and momentum parameters under which the ASG method is guaranteed to converge for any smooth strongly-convex finite-sum, but where accelerated rates of convergence are no longer guaranteed. Our analysis approach leads to new bounds on the convergence rate of SGD in the finite-sum setting, under the assumption that each term $f_i$ is smooth, strongly-convex, and twice continuously differentiable.

2. Preliminaries and Analysis Framework

In this section we establish a basic framework for analyzing the AG method. Then we specialize it to the stochastic approximation and finite-sum setting settings, respectively, in Sections 3 and 4.

Throughout this paper we assume that $f$ is twice-continuously differentiable, $L$-smooth, and $\mu$-strongly convex, with $0 < \mu \leq L$; see e.g., Nesterov (2004); Bubeck (2015). Examples of typical tasks satisfying these assumptions are $\ell_2$-regularized logistic regression and $\ell_2$-regularized least-squares regression (i.e., ridge regression). Taken together, these properties imply that the Hessian $\nabla^2 f(x)$ exists, and for all $x \in \mathbb{R}^d$ the eigenvalues of $\nabla^2 f(x)$ lie in the interval $[\mu, L]$. Also, recall that $x^*$ denotes the unique minimizer of $f$ and $f^* = f(x^*)$.

In contrast to all previous work we are aware of, our analysis focuses on the sequence $(y_k)_{k \geq 0}$ generated by the method (2)–(3). Let $r_k := y_k - x^*$ denote the suboptimality of the current iterate, and let $v_k := x_k - x_{k-1}$ denote the velocity.

Substituting the definition of $y_{k+1}$ from (2) into (3) and rearranging, we obtain

$$v_{k+1} = \beta v_k - \alpha g_{k+1}.$$  

By using the definition of $v_k$, substituting (7) and (3) into (2), and rearranging, we also obtain that

$$r_{k+1} = r_k + \beta^2 v_{k-1} - \alpha (1 + \beta) g_k.$$  

Combining (7) and (8), we get the recursion

$$\begin{bmatrix} r_{k+1} \\ v_k \\ \end{bmatrix} = \begin{bmatrix} I & \beta^2 I \\ 0 & \beta I \\ \end{bmatrix} \begin{bmatrix} r_k \\ v_{k-1} \\ \end{bmatrix} - \alpha \begin{bmatrix} (1 + \beta) I \\ I \\ \end{bmatrix} g_k.$$  

(9)

Note that $r_1 = x_0 - x^*$ and $v_0 = 0$ based on the common convention that $x_{-1} = x_0$.

Our analysis below will build on the recursion (9) and will also make use of the basic fact that if $f : \mathbb{R}^d \to R$ is twice continuously differentiable then for all $x, y \in \mathbb{R}^d$

$$\nabla f(y) = \nabla f(x) + \int_0^1 \nabla^2 f(x + t(y - x)) dt (y - x).$$  

(10)

3. The Stochastic Approximation Setting

Now consider the stochastic approximation setting. We assume, for all $k$, that $g_k$ is a random vector satisfying

$$\mathbb{E}[g_k] = \nabla f(y_k)$$

and that there is a finite constant $\sigma^2$ such that

$$\mathbb{E} \left[ \|g_k - \nabla f(y_k)\|^2 \right] \leq \sigma^2.$$

Let $\zeta_k = g_k - \nabla f(y_k)$ denote the gradient noise at iteration $k$, and suppose that these gradient noise terms are mutually independent. Applying (10) with $y = y_k$ and $x = x^*$, we get that

$$g_k = H_k r_k + \zeta_k, \quad \text{where} \quad H_k = \int_0^1 \nabla^2 f(x^* + tr_k) dt.$$  

Using this in (9), we find that $r_k$ and $v_k$ evolve according to

$$\begin{bmatrix} r_{k+1} \\ v_k \\ \end{bmatrix} = A_k \begin{bmatrix} r_k \\ v_{k-1} \\ \end{bmatrix} - \alpha \begin{bmatrix} (1 + \beta) I \\ I \\ \end{bmatrix} \zeta_k,$$  

(11)

where

$$A_k = \begin{bmatrix} I - \alpha (1 + \beta) H_k & \beta^2 I \\ -\alpha H_k & \beta I \end{bmatrix}.$$  

(12)

Unrolling the recursion (11), we get that

$$\begin{bmatrix} r_{k+1} \\ v_k \\ \end{bmatrix} = (A_k \cdots A_1) \begin{bmatrix} x_0 - x^* \\ 0 \\ \end{bmatrix} - \alpha \begin{bmatrix} (1 + \beta) I \\ I \end{bmatrix} \zeta_k - \alpha \sum_{j=1}^{k-1} (A_k \cdots A_{j+1}) \begin{bmatrix} (1 + \beta) I \\ I \end{bmatrix} \zeta_j,$$  

(13)

from which it is clear that we may expect convergence properties to depend on the matrix products $A_k \cdots A_j$.

3.1. The quadratic case

We can explicitly bound the matrix product in the specific case where $f(x) = \frac{1}{2} x^\top H x - b^\top x + c$, for a symmetric matrix $H \in \mathbb{R}^{d \times d}$, and with $b \in \mathbb{R}^d$ and $c \in \mathbb{R}$. In this case, (13) simplifies to

$$\begin{bmatrix} r_{k+1} \\ v_k \\ \end{bmatrix} = A_k \begin{bmatrix} x_0 - x^* \\ 0 \\ \end{bmatrix} - \alpha \sum_{j=1}^{k-1} A^{k-j} \begin{bmatrix} (1 + \beta) I \\ I \end{bmatrix} \zeta_j,$$  

(14)

where

$$A = \begin{bmatrix} I - \alpha (1 + \beta) H & \beta^2 I \\ -\alpha H & \beta I \end{bmatrix}.$$  

(15)
We obtain an error bound by ensuring that the spectral radius \( \rho(A) \) of \( A \) is less than 1. In this case we recover the well-known rate for ASG in the deterministic setting. Let \( \Delta_\lambda = (1 + \beta)^2(1 - \alpha \lambda)^2 - 4\beta(1 - \alpha \lambda) \) and define

\[
\rho_\lambda(\alpha, \beta) = \left\{ \begin{array}{ll}
\frac{1}{2} ||(1 + \beta)(1 - \alpha \lambda)|| + \frac{1}{2} \sqrt{\Delta_\lambda} & \text{if } \Delta_\lambda \geq 0, \\
\sqrt{\beta(1 - \alpha \lambda)} & \text{otherwise}.
\end{array} \right.
\]

**Theorem 1.** Let \( \rho(\alpha, \beta) = \max\{\rho_\mu(\alpha, \beta), \rho_L(\alpha, \beta)\} \). If \( \alpha \) and \( \beta \) are chosen so that \( \rho(\alpha, \beta) < 1 \), then for any \( \epsilon > 0 \), there exists a constant \( C_\epsilon \) such that, for all \( k \),

\[
\mathbb{E} \left[ ||y_{k+1} - x^*||^2 \right] \leq C_\epsilon \left( (\rho(\alpha, \beta) + \epsilon)^{2k} ||x_0 - x^*||^2 + \frac{\alpha^2((1 + \beta)^2 + 1)}{1 - \rho(\alpha, \beta)^2} \sigma^2 \right).
\]

Theorem 1 holds with respect to all norms; the constant \( C_\epsilon \) depends on \( \epsilon \) and the choice of norm. Theorem 1 shows that ASG converges at a linear rate to a neighborhood of the minimizer of \( f \) that is proportional to \( \sigma^2 \). The proof is given in Appendix A of the supplementary material, and we provide numerical experiments in Section 3.2 to analyze the tightness of the convergence rate and coefficient multiplying \( \sigma^2 \) in Theorem 1. Comparing to Aybat et al. (2019), we recover the same rate, despite taking a different approach, and the coefficient multiplying \( \sigma^2 \) in Theorem 1 is smaller.

**Corollary 1.1.** Suppose that \( \alpha = 1/L \) and \( \beta = \frac{\sqrt{Q} - 1}{\sqrt{Q} + 1} \). Then for all \( k \),

\[
\mathbb{E}[f(y_{k+1})] - f^* \leq \frac{L}{2} \left( \frac{\sqrt{Q} - 1}{\sqrt{Q}} + \epsilon_k \right)^{2k} ||x_0 - x^*||^2 + \frac{C_\epsilon}{2L} \frac{5Q^2 + 2Q^{3/2} + Q}{(\sqrt{Q} - 1)(\sqrt{Q} + 1)} \sigma^2,
\]

where \( \epsilon_k \sim (\sqrt{K} - 1) \).

**Theorem 2.** Let \( f \) be \( L \)-smooth, \( \mu \)-strongly-convex, and twice continuously-differentiable (not necessarily quadratic). Suppose that \( \alpha = \frac{2}{\mu + L} \) and \( \beta = 0 \). Then for all \( k \),

\[
\mathbb{E}[f(y_{k+1})] - f^* \leq \frac{L}{2} \left( \frac{Q - 1}{Q + 1} \right)^{2k} ||x_0 - x^*||^2 + \frac{Q\sigma^2}{2L}.
\]

Corollary 1.1 confirms that, with the standard choice of parameters, ASG converges at an accelerated rate to a region of the optimizer. Comparing with Theorem 2, which is proved in Appendix B, we see that in the stochastic approximation setting, with bounded variance, ASG not only converges at a faster rate than SGD, the factor multiplying \( \sigma^2 \) also scales more favorably, \( \mathcal{O}\left(\sqrt{Q}\sigma^2\right) \) for ASG vs. \( \mathcal{O}\left(Q\sigma^2\right) \) for SGD.

### 3.2. Numerical Experiments

In Figure 1 we visualize runs of the ASG method on a least-squares regression problem for different problem condition numbers \( Q \). The objective \( f \) corresponds to the worst-case quadratic function used to construct the lower bound \( (6) \) (Nesterov, 2004), for dimension \( d = 100 \). Stochastic gradients are sampled by adding zero-mean Gaussian noise with variance \( \sigma^2 = 0.0025 \) to the true gradient. The left plots in each sub-figure depict theoretical predictions from Theorem 1, while the right plots in each sub-figure depict empirical results. Each pixel corresponds to an independent run of the ASG method for a specific choice of constant step-size and momentum parameters. In all figures, the area enclosed by the red contour depicts the theoretical stability region from Theorem 1 for which \( \rho(\alpha, \beta) < 1 \).

Figures 1a/1c/1e showcase the coefficient multiplying the variance term, which is taken to be \( \frac{\alpha^2((1 + \beta)^2 + 1)}{1 - \rho(\alpha, \beta)^2} \) in theory. Brighter regions correspond to smaller coefficients, while darker regions correspond to larger coefficients. All sets of figures (theoretical and empirical) use the same color scale. We can see that the coefficient of the variance term in Theorem 1 provides a good characterization of the magnitude of the neighbourhood of convergence. The constant \( C_\epsilon \) is approximated as \( 1 + (1 - \rho(\alpha, \beta)^2)(||A||^2 - \rho(\alpha, \beta)^2) \), where \( ||A|| \) denotes the largest singular value of \( A \) in \( (15) \), and \( \rho(\alpha, \beta) \) is the largest eigenvalue of \( A \). More detail on this simple approximation is provided in Appendix A.1 of the supplementary material.

Figures 1b/1d/1f showcase the linear convergence rate in theory and in practice. Brighter regions correspond to faster rates, and darker regions correspond to slower rates. Again, all figures (theoretical and empirical) use the same color scale. We can see that the theoretical linear convergence rates in Theorem 1 provide a good characterization of the empirical convergence rates. Moreover, the theoretical conditions for convergence in Theorem 1 depicted by the red-contour appear to be tight.

In short, the theory developed in this section appears to provide an accurate characterization of the ASG method in the stochastic-approximation setting. As we will see in the subsequent section, this theoretical characterization does not reflect its behavior in the finite-sum setting, which is typically closer to practical machine-learning setups, where randomness is due to mini-batching.

### 4. The Finite-Sum Setting

Now consider the finite-sum setting, with

\[
f(x) = \frac{1}{n} \sum_{i=1}^{n} f_i(x),
\]
On the Convergence of Nesterov’s Accelerated Gradient Method

where each function $f_i$ is $\mu$-strongly convex, $L$-smooth, and twice continuously differentiable. In this setting, stochastic gradients $g_k$ are obtained by sampling a subset of terms. This can be seen as approximating the gradient $\nabla f(y_k)$ with a mini-batch gradient

$$ g_k = \sum_{i=1}^{n} \nu_{k,i} \nabla f_i(y_k), \quad (17) $$

where $\nu_k \in \mathbb{R}^n$ is a sampling vector with components $\nu_{k,i}$ satisfying $E[\nu_{k,i}] = \frac{1}{n}$ (Gower et al., 2019). To simplify the discussion, let us assume that the mini-batch sampled at every iteration $k$ has the same size, and all elements are given the same weight, so $\sum_{i=1}^{n} \nu_{k,i} = 1$, those indices $i$ which are sampled have $\nu_{k,i} = \frac{1}{m}$ where $m$ is the mini-batch size ($1 \leq m \leq n$), and $\nu_{k,i} = 0$ for all other indices.

4.1. An Impossibility Result

Next we show that even when each function $f_i$ is well-behaved, the ASG method may diverge when using the standard choice of step-size and momentum. Instability of Nesterov’s method for convex (but not strongly convex) functions with unbounded eigenvalues is shown in Liu & Belkin (2020). This section employs a different proof technique to strengthen this result to the case where each function $f_i$ is $\mu$-strongly-convex and $L$-smooth (all eigenvalues bounded between $\mu$ and $L$).

Let us assume that we do not see the same mini-batch twice consecutively; i.e.,

$$ \mathbb{P}(|\nu_{k+1} - \nu_k| > 0) = 1 \quad \text{for all } k. \quad (18) $$

Figure 1. Visualizing the accuracy with which the theory predicts the coefficient of the variance term and the convergence rate for different choices of constant step-size and momentum parameters, and various objective condition numbers $Q$. Plots labeled “Theoretical” depict theoretical results from Theorem 1. Plots labeled “Empirical” depict empirical results when using the ASG method to solve a least-squares regression problem with additive Gaussian noise; each pixel corresponds to an independent run of the ASG method for a specific choice of constant step-size and momentum parameters. In all figures, the area enclosed by the red contour depicts the theoretical stability region from Theorem 1 for which $\rho(\alpha, \beta) < 1$. Fig. 1a/1c/1e: Pixel intensities correspond to the coefficient of the variance term in Theorem 1 ($\lim_{k\to\infty} \frac{1}{2} \mathbb{E} \|y_k - x^*\|^2$), which provides a good characterization of the magnitude of the neighbourhood of convergence, even without explicit knowledge of the constant $C_r$. Brighter regions correspond to smaller coefficients, while darker regions correspond to larger coefficients. Fig. 1b/1d/1f: Pixel intensities correspond to the theoretical convergence rates in Theorem 1, which provides a good characterization of the empirical convergence rates. Brighter regions correspond to faster rates, and darker regions correspond to slower rates. The theoretical conditions for convergence in Theorem 1 depicted by the red-contour are tight.
It is typical in practice to perform training in epochs over the data set, and to randomly permute the data set at the beginning of each epoch, so it is unlikely to see the same mini-batch twice in a row. Note we have not assumed that the sample vectors \( \nu_k \) are independent. We do assume that \( \mathbb{E}_k[\nu_{k,i}] = \frac{1}{n} \), where \( \mathbb{E}_k \) denotes expectation with respect to the marginal distribution of \( \nu_k \).

The interpolation condition is said to hold if the minimizer \( x^* \) of \( f \) also minimizes each \( f_i \); i.e., if \( \nabla f_i(x^*) = 0 \) for all \( i = 1, \ldots, n \). It has been observed in some settings that stronger convergence guarantees can also be obtained when interpolation or a related assumption holds; e.g., (Schmidt & Le Roux, 2013; Loizou & Richtárik, 2017; Ma et al., 2018; Vaswani et al., 2019).

**Theorem 3.** Suppose we run the ASG method (2)–(3) in a finite-sum setting where \( n \geq 3 \) and the sampling vectors \( \nu_k \) satisfy the condition (18). For any initial point \( x_0 \in \mathbb{R}^d \), there exist \( L \)-smooth, \( \mu \)-strongly convex quadratic functions \( f_1, \ldots, f_n \) such that \( f \) is also \( L \)-smooth and \( \mu \)-strongly convex, and if we run the ASG method with \( \alpha = 1/L \) and \( \beta = \sqrt{\frac{L}{\mu} - 1} \), then

\[
\lim_{k \to \infty} \mathbb{E}[\|y_k - x^*\|] = \infty.
\]

This is true even if the functions \( f_1, \ldots, f_n \) are required to satisfy the interpolation condition.

**Proof.** We will prove this claim constructively. Given the initial vector \( x_0 \), choose \( x^* \in \mathbb{R}^d \) to be any vector \( x^* \neq x_0 \).

Let \( U \) be an orthogonal matrix. Let the Hessian matrices \( H_i \), \( i = 1, \ldots, n \), be chosen so that they are all diagonalized by \( U \), and let \( \Lambda_i \) denote the diagonal matrix of eigenvalues of \( H_i \); i.e., \( H_i = U \Lambda_i U^\top \). Denote by \( \Lambda_{\nu_k} \) the matrix

\[
\Lambda_{\nu_k} = \sum_{i=1}^n \nu_{k,i} \Lambda_i.
\]

It follows that \( \Lambda_{\nu_k} \in \mathbb{R}^{d \times d} \) is also diagonal, and all of its diagonal entries are in \( [\mu, L] \).

Recall that we have assumed that the functions \( f_i \) are quadratic: \( f_i(x) = \frac{1}{2} x^\top H_i x - b_i^\top x + c_i \). Let us assume that \( b_i \in \mathbb{R}^d \) and \( c_i \in \mathbb{R} \) are chosen so that all functions \( f_i \) are minimized at the same point \( x^* \), satisfying the interpolation condition. Then from (10), we have

\[
g_k = U \Lambda_{\nu_k} U^\top r_k.
\]

Using this in (9) and unrolling, we obtain that

\[
\begin{bmatrix}
  r_{k+1} \\
  v_k
\end{bmatrix} = A_k A_{k-1} \cdots A_1 \begin{bmatrix}
  v_1 \\
  v_0
\end{bmatrix},
\]

where

\[
A_j = \begin{bmatrix}
  I & -\alpha(1 + \beta) U \Lambda_{\nu_j} U^\top & \beta^2 I \\
  -\alpha U \Lambda_{\nu_j} U^\top & \beta I
\end{bmatrix}.
\]

For fixed \( n \) and \( m \), there are a finite number of sampling vectors \( \nu_k \) (precisely \( \binom{m}{n} \)), and therefore the matrices \( A_j \) belong to a closed bounded set \( \mathcal{A} \). It follows that the trajectory \( \{[r_{k+1}, v_k]^\top \}_{k \geq 0} \) is stable if the joint spectral radius of the set of matrices \( \mathcal{A} \) is less than one (Rota & Strang, 1960). Conversely, if \( \mathbb{E}[\rho(A_k \cdots A_1)^{1/k}] > 1 \) for all \( k \) sufficiently large, then \( \lim_{k \to \infty} ||y_k - x^*|| = \infty \).

Based on the construction above, the norm of the matrix product \( A_k \cdots A_1 \) in (21) can be characterized by studying products of smaller \( 2 \times 2 \) matrices of the form

\[
B(\lambda_{k,j}) = \begin{bmatrix}
  1 - \alpha(1 + \beta) & \beta^2 \\
  -\alpha \lambda_{k,j} & \beta
\end{bmatrix},
\]

where \( \lambda_{k,j} \) is a diagonal entry of \( \Lambda_{\nu_k} \). To see this, observe that there is a permutation matrix \( P \in \{0, 1\}^{2d \times 2d} \) such that (see Appendix C)

\[
P \begin{bmatrix}
  U^\top & 0 \\
  0 & U^\top
\end{bmatrix} A_j U \begin{bmatrix}
  U & 0 \\
  0 & U
\end{bmatrix} P^\top
\]

\[
= \begin{bmatrix}
  B(\lambda_{j,1}) & 0 & \cdots & 0 \\
  0 & B(\lambda_{j,2}) & \cdots & 0 \\
  \vdots & \vdots & \ddots & \vdots \\
  0 & 0 & \cdots & B(\lambda_{j,d})
\end{bmatrix},
\]

where \( \lambda_{j,i} \) is the \( i \)th diagonal entry of \( \Lambda_{\nu_j} \).

Furthermore, since all matrices \( H_i \) have the same eigenvectors, we have that

\[
P \begin{bmatrix}
  U^\top & 0 \\
  0 & U^\top
\end{bmatrix} A_k A_{k-1} \cdots A_1 U \begin{bmatrix}
  U & 0 \\
  0 & U
\end{bmatrix} P^\top
\]

\[
= \begin{bmatrix}
  T_{k,1} & 0 & \cdots & 0 \\
  0 & T_{k,2} & \cdots & 0 \\
  \vdots & \vdots & \ddots & \vdots \\
  0 & 0 & \cdots & T_{k,d}
\end{bmatrix},
\]

where \( T_{k,j} = B(\lambda_{k,j}) \cdots B(\lambda_{j,1}) \). Hence, the spectral radius of the product \( A_k \cdots A_1 \) corresponds to the maximum spectral radius of any of the \( 2 \times 2 \) matrices \( T_{k,j} \), \( j = 1, \ldots, d \).

Let \( j \) index a subspace such that \( u_j^\top c_1 \neq 0 \), where \( u_j \) is the \( j \)th column of \( U \). To simplify the discussion, suppose that all mini-batches are of size \( m = 1 \), and assume \( n > 1 \). Since we can define the Hessians of the functions \( f_i \) such that the eigenvalues pair together arbitrarily, consider matrix products of the form

\[
T_{k,j} = B(L)B(\mu)^{k_1}B(L)B(\mu)^{k_2} \cdots B(L)B(\mu)^{k_s},
\]

where \( k = k_1 + \cdots + k_s + s \). That is, all but one of the functions \( f_i \) have the eigenvalue \( \mu \) in this subspace, and the remaining one has eigenvalue \( L \) in this subspace. Hence, most of the time we sample mini-batches corresponding to \( B(\mu) \),
On the Convergence of Nesterov’s Accelerated Gradient Method

The divergence result in Theorem 3 stems from the fact that the algorithm acquires momentum along a low-curvature direction, and then, suddenly, a high-curvature mini-batch is sampled that overshoots along the current trajectory. Momentum prevents the iterates from immediately adapting to the overshoot, and propels the iterates away from the minimizer for several consecutive iterations.

To illustrate this effect, consider the following example finite-sum problem with $d = 3$, where each function $f_i$ is a strongly-convex quadratic with gradient

$$\nabla f_i(x) = U A_i U^T (x - x^*).$$

For simplicity, take $U = I$, and let

$$A_i = \begin{bmatrix} L & 0 & 0 \\ 0 & \mu & 0 \\ 0 & 0 & \lambda_1 \end{bmatrix}.$$  

The scalar $\lambda_1$ is equal to $\mu$ for all $i \neq n$, and is equal to $L$ for $i = n$. Therefore, each function $f_i$ is $\mu$-strongly convex, $L$-smooth, and minimized at $x^*$, and the global objective $f$ is also $\mu$-strongly convex, $L$-smooth, and minimized at $x^*$. Moreover, the functions $f_i$ are nearly all identical, except for $f_n$, which we refer to as the inconsistent mini-batch.

From the proof of Theorem 3, the growth rate of the iterates along the third coordinate direction, with the usual choice of parameters ($\alpha = 1/L$, $\beta = (\sqrt{Q} - 1)/(\sqrt{Q} + 1)$), is

$$\mathbb{E}[\rho(A_k \cdots A_1)^{1/k}] \sim \left( \frac{\sqrt{Q} - 1}{\sqrt{Q}} \right) (n - 1)^{\frac{1}{2}}.$$

Notice that the term $(n - 1)^{\frac{1}{2}}$ goes to 1 as $n$ grows to infinity. Hence, for a fixed condition number $Q$, the ASG method exhibits an increased probability of convergence as...
n becomes large. The intuition for this is that we sample the inconsistent mini-batch less frequently, and thereby decrease the likelihood of derailing convergence.

Figure 2 illustrates the convergence of the ASG method in this setting with the usual choice of parameters \((\alpha = \frac{1}{L}, \beta = \frac{\sqrt{n}-1}{\sqrt{n}+1})\), for various \(n\) (number of terms in the finite-sum). At each iteration, the ASG method obtains a stochastic gradient by sampling a mini-batch from the finite-sum. Components of iterates along the first coordinate direction converge in a finite number of steps, and components of iterates along the second coordinate direction converge at Nesterov’s rate \((\sqrt{n}-1)/\sqrt{n}\). Meanwhile, components of iterates along the third coordinate direction diverge.

Annotated red points indicate iterations at which the mini-batch corresponding to the function \(f_n\) was sampled. The shaded windows illustrate that immediately after the inconsistent mini-batch is sampled, the gradient and momentum buffer have opposite signs for several consecutive iterations.

### 4.3. Convergent Parameters

Next we turn our attention to finding alternative settings for the parameters \(\alpha\) and \(\beta\) in the ASG method which guarantee convergence in the finite-sum setting. Vaswani et al. (2019) obtain linear convergence under a strong growth condition using an alternative formulation of ASG which has multiple momentum parameters by keeping the step-size constant and having the momentum parameters vary. Here we focus on constant step-size and momentum and make no assumptions about growth.

Our approach is to bound the spectral norm of the products \(\|A_k \cdots A_j\|\) using submultiplicativity of matrix norms. This recovers linear convergence to a neighborhood of the minimizer, but the rate is no longer accelerated.

Define the quantities
\[
C_\lambda(\alpha, \beta) = (1 - \alpha(1 + \beta))\lambda^2 + \alpha^2\lambda^2 + \beta^2(\beta^2 + 1)
\]
\[
\Delta_\lambda(\alpha, \beta) = C_\lambda(\alpha, \beta) - 4\beta^2(1 - \alpha\lambda)^2
\]
\[
R_\lambda(\alpha, \beta) = \frac{1}{\sqrt{2}} \left( C_\lambda(\alpha, \beta) + \sqrt{\Delta_\lambda(\alpha, \beta)} \right)^{1/2}
\]
and let \(R(\alpha, \beta) = \max_{\lambda \in [\mu, L]} R_\lambda(\alpha, \beta)\).

**Theorem 4.** Let \(\alpha\) and \(\beta\) be chosen so that \(R(\alpha, \beta) < 1\). Then for all \(k \geq 0\),
\[
\mathbb{E} \|y_{k+1} - x^*\| \leq R(\alpha, \beta)^k \|y_0 - x^*\| + \frac{\alpha}{1 - R(\alpha, \beta)} \sigma,
\]
where \(\sigma = \frac{1}{n} \sum_{i=1}^n \|\nabla f_i(x^*)\|\).

Theorem 4 is proved in Appendix E for general \(L\)-smooth \(\mu\)-strongly-convex functions. Note that if an interpolation condition holds (a weaker assumption than the strong growth condition), then \(\sigma = 0\).

Theorem 4 shows that the ASG method can be made to converge in the finite-sum setting for \(L\)-smooth \(\mu\)-strongly convex objective functions when run with constant stepsizes. In particular, the algorithm converges at a linear rate to a neighborhood of the minimizer that is proportional to the variance of the noise terms. Note that this theorem also allows for negative momentum parameters. Using the spectral norm to guarantee stability is restrictive, in that it is sufficient but not necessary. There may be values of \(\alpha\) and \(\beta\) for which \(R(\alpha, \beta) \geq 1\) and the algorithm still converges. Having \(R(\alpha, \beta) < 1\) ensures that \(\|r_k\| + \|v_k\|\) decreases at every iteration.

**Corollary 4.1.** Suppose that \(\alpha < \frac{2}{L}\) and \(\beta = 0\). Then for all \(k \geq 0\)
\[
\mathbb{E} \|y_k - x^*\| \leq \rho(\alpha)^k \|y_0 - x^*\| + \frac{\alpha}{1 - \rho(\alpha)} \sigma,
\]
where \(\rho(\alpha) := \max_{\lambda \in [\mu, L]} |1 - \alpha\lambda|\).

Corollary 4.1 is proved in Appendix F for smooth strongly-convex functions, and shows the convergence of SGD in the finite-sum setting without making any assumptions on the noise distribution.

**Corollary 4.2.** Suppose that \(\alpha = \frac{2}{\mu + L}\) and \(\beta = 0\). Then for all \(k \geq 0\)
\[
\mathbb{E} \|y_k - x^*\| \leq \left( \frac{Q - 1}{Q + 1} \right)^k \|y_0 - x^*\| + \frac{1}{\mu} \sigma.
\]
Corollary 4.2. is proved in Appendix F for smooth strongly-convex functions, and shows that SGD converges to a neighborhood of \(x^*\) at the same linear rate as GD, viz. (4), in the finite-sum setting, without making any assumptions on the noise distribution, such as the strong-growth condition; a novel result to the best of our knowledge. Moreover, when the interpolation condition holds, we have that \(\sigma = 0\).

Figure 3 illustrates the tightness of the convergence rate and variance bound in Corollary 4.2 when minimizing randomly generated least-squares problems with various condition numbers. The finite-sum least-squares problem consists of 25000 data samples, with 2 features each, partitioned into 50 mini-batches, each with condition number \(Q\). At each iteration, one of the 50 mini-batches is sampled to compute a stochastic gradient step. Dashed lines indicate the theoretical convergence rate and variance bound from Corollary 4.2. Solid lines indicate the empirical convergence observed in practice. The convergence rate and variance bound in Corollary 4.2 provide a tight characterization of the SGD convergence observed in practice.
On the Convergence of Nesterov’s Accelerated Gradient Method

Figure 3. Visualizing the accuracy with which Corollary 4.2 predicts the theoretical convergence of SGD with step-size $\alpha = 2/(\mu + L)$ in the finite-sum setting, when minimizing randomly generated least-squares problems with various condition numbers $Q$. The finite-sum problem consists of 25000 data samples, with 2 features each, partitioned into 50 mini-batches, each with condition number $Q$. At each iteration one of the 50 mini-batches is sampled to compute a stochastic gradient step. Dashed lines indicate the theoretical convergence rate and variance bound from Corollary 4.2. Solid lines indicate the empirical convergence observed in practice. The convergence rate and variance bound in Corollary 4.2 is tight.

5. Conclusions

This paper contributes to a broader understanding of the ASG method in stochastic settings. Although the method behaves well in the stochastic approximation setting, it may diverge in the finite-sum setting when using the usual step-size and momentum. This emphasizes the important role the bounded variance assumption plays in the stochastic approximation setting, since a similar condition does not necessarily hold in the finite-sum setting. Forsaking acceleration guarantees, we provide conditions under which the ASG method is guaranteed to converge in the smooth strongly-convex finite-sum setting with constant step-size and momentum, without assuming any growth or interpolation condition.

We believe there is scope to obtain tighter convergence bounds for the ASG method with constant step-size and momentum in the finite-sum setting. Convergence guarantees using the joint spectral radius are likely to provide the tightest and most intuitive bounds, but are also difficult to obtain. To date, Lyapunov-based proof techniques have been the most fruitful in the literature.

We also believe that there is scope to improve the robustness of Nesterov’s method to inconsistent mini-batches in the finite-sum setting. For example, adaptive restarts, which have been show to improve the convergence rate of Nesterov’s method (O’Donoghue & Candès, 2015) with deterministic gradients, may also be able to mitigate the divergence behaviour identified in this paper.

We also believe that future work understanding the role that negative momentum parameters play in practice may lead to improved optimization of machine learning models. All convergence guarantees and variance bounds in this paper hold for both positive and negative momentum parameters.

Our variance bounds and theoretical rates support the observation that negative momentum parameters may slow-down convergence, but can also lead to non-trivial variance reduction. Previous work has found negative momentum to be useful in asynchronous distributed optimization (Miliathas et al., 2016) and for stabilizing adversarial training (Gidel et al., 2018). Although it is almost certainly not possible (in general) to obtain zero variance solutions by only using negative momentum parameters, for Deep Learning practitioners that already use the ASG method to train their models, perhaps momentum schedules incorporating negative values towards the end of training can improve performance.
