UneVEn: Universal Value Exploration for Multi-Agent Reinforcement Learning

Tarun Gupta 1  Anuj Mahajan 1  Bei Peng 1  Wendelin Böhmer 2  Shimon Whiteson 1

Abstract
VDN and QMIX are two popular value-based algorithms for cooperative MARL that learn a centralized action value function as a monotonic mixing of per-agent utilities. While this enables easy decentralization of the learned policy, the restricted joint action value function can prevent them from solving tasks that require significant coordination between agents at a given timestep.

We show that this problem can be overcome by improving the joint exploration of all agents during training. Specifically, we propose a novel MARL approach called Universal Value Exploration (UneVEn) that learns a set of related tasks simultaneously with a linear decomposition of universal successor features. With the policies of already solved related tasks, the joint exploration process of all agents can be improved to help them achieve better coordination. Empirical results on a set of exploration games, challenging cooperative predator-prey tasks requiring significant coordination among agents, and StarCraft II micromanagement benchmarks show that UneVEn can solve tasks where other state-of-the-art MARL methods fail.

1. Introduction
Learning control policies for cooperative multi-agent reinforcement learning (MARL) remains challenging as agents must search the joint action space, which grows exponentially with the number of agents. Current state-of-the-art value-based methods such as VDN (Sunehag et al., 2017) and QMIX (Rashid et al., 2020b) learn a centralized joint action value function as a monotonic factorization of decentralized agent utility functions. Due to this monotonic factorization, the joint action value function can be decentralized maximized as each agent can simply select the action that maximizes its corresponding utility function, known as the Individual Global Maximum principle (IGM, Son et al., 2019).

This monotonic restriction cannot represent the value of all joint actions and an agent’s utility depends on the policies of the other agents (nonmonotonicity, Mahajan et al., 2019). Even in collaborative tasks this can exhibit relative overgeneralization (RO, Panait et al., 2006), when the optimal action’s utility falls below that of a suboptimal action (Wei et al., 2018; 2019). While this pathology depends in practice on the agents’ random experiences, we show in Section 2 that in expectation RO prevents VDN from learning a large set of predator-prey games during the critical phase of uniform exploration.

QTRAN (Son et al., 2019) and WQMIX (Rashid et al., 2020a) show that this problem can be avoided by weighting the joint actions of the optimal policy higher. They propose to deduce this weighting from an unrestricted joint value function that is learned simultaneously. However, this unrestricted value is only a critic of the factored model, which itself is prone to RO, and often fails in practice due to insufficient $\epsilon$-greedy exploration. MAVEN (Mahajan et al., 2019) improves exploration by learning an ensemble of monotonic joint action value functions through committed exploration and maximizing diversity in the joint team behavior. However, it does not specifically target optimal actions and may not work in tasks with strong RO.

The core idea of this paper is that even when a target task exhibits RO under value factorization, there may be similar tasks that do not. If their optimal actions overlap in some states with the target task, executing these simpler tasks can implicitly weight exploration to overcome RO. We call this novel paradigm Universal Value Exploration (UneVEn).

To learn different MARL tasks simultaneously, we extend Universal Successor Features (USFs, Borsa et al., 2018) to Multi-Agent USFs (MAUSFs), using a VDN decomposition. During execution, UneVEn samples task descriptions from a Gaussian distribution centered around the target and executes the task with the highest value. This biases exploration towards the optimal actions of tasks that are similar but have
already been solved. Sampling these reduces RO for every task that shares the same optimal action and thus increases the number of solvable tasks, eventually overcoming RO for the target task, too. This is the different from exploration methods like MAVEN, which keep the task same but reweigh explorative behaviours using the task returns. We show in Section 2 on a classic RO example that UneVEn can gradually increase the set of solvable tasks until it includes the target task.

We evaluate our novel approach against several ablations in predator-prey tasks that require significant coordination amongst agents and highlight the RO pathology, as well as other commonly used benchmarks like StarCraft II (Panait et al., 2006) in the rewarded state value-based methods on target tasks that exhibit strong RO in predator-prey tasks that require significant coordination amongst agents and highlight the RO pathology, as well as other commonly used benchmarks like StarCraft II (Samvelyan et al., 2019). We also show empirically that UneVEn significantly outperforms current state-of-the-art value-based methods on target tasks that exhibit strong RO and in zero-shot generalization (Borsa et al., 2018) to other reward functions.

2. Illustrative Example

Figure 1 sketches a simplified predator-prey task where two agents (blue and magenta) can both move left or right \((L/R)\) and execute a special ‘catch’ \((C)\) action when they both stand next to the stationary prey \((r)\). The agents are collaboratively rewarded (shown on the right of Figure 1) +7 when they catch the prey together and punished \(-p\) if they attempt it alone, both ending the episode. For large \(p\), both VDN and QMIX can lead to relative overgeneralization (Dec-POMDP, Oliehoek et al., 2016) in the rewarded state \(s\) when agent 1’s utility \(Q^1(s, u^1)\) of the catch action \(u^1 = C\) drops below that of the movement actions \(u^1 \in \{L, R\}\). At the beginning of training, when the value estimates are near zero and both agents explore random actions, we have:

\[
Q^1(s, C) < Q^1(s, L/R) \Rightarrow r < p \left(\frac{1}{\pi^s(C|s)} - 2\right) + c,
\]

where \(c\) is a constant that depends mainly on future values.

See Appendix A for a formal derivation. The threshold at which \(p\) yields RO depends strongly on agent 2’s probability of choosing \(u^2 = C\), i.e., \(\pi^s(C|s)\). For uniform exploration, this criterion is fulfilled if \(p > r\), but reinforcing other actions than \(u^2 = C\) can lower this threshold significantly. However, if agent 2 chooses \(u^2 = C\) for more than half of its actions, no amount of punishment can prevent learning of the correct greedy policy.

Figure 2 plots the entire task space w.r.t. \(p\) and \(r\), marking the set of tasks solvable under uniform exploration \((\pi^2(C|s) = \frac{1}{4})\) are green, shades of red represent tasks that on average exhibit RO for different \(\pi^2(C|s)\).

3. Background

A fully cooperative multi-agent task can be formalized as a decentralized partially observable Markov decision process (Dec-POMDP, Oliehoek et al., 2016) consisting of a tuple \(G = (S, U, R, \Omega, O, n, \gamma)\). \(s \in S\) describes the true state of the environment. At each time step, each agent \(a \in A \equiv \{1, ..., n\}\) chooses an action \(u^a \in U\) forming a joint action \(u \in U \equiv U^n\). This causes a transition in the environment according to the state transition kernel \(P(s', u) : S \times U \times S \to [0, 1]\). All agents are collaborative and share therefore the same reward function \(R(s, u) : S \times U \to \mathbb{R}\). \(\gamma \in [0, 1]\) is a discount factor.

Due to partial observability, each agent \(a\) cannot observe the true state \(s\), but receives an observation \(o^a \in \Omega\) drawn from observation kernel \(o^a \sim O(s, a)\). At time \(t\), each agent \(a\) has access to its action-observation history \(\tau^a_t \in \mathbb{T}^a \equiv \Omega \times \Upsilon^a \times \Omega\), on which it conditions a stochastic policy \(\pi^a(u^a | \tau^a_t)\). \(\tau^a_t \in U^n\) denotes the histories of all agents. The joint stochastic policy \(\pi(u | s_t, \tau^a_t) = \prod_{a=1}^n \pi^a(u^a | \tau^a_t)\) induces a joint action value function \(Q^T(s_t, \tau^a_t, u) = E[G_t | s_t, \tau^a_t, u]\), where \(G_t = E[G_{t+1} | r_{t+1} = \gamma^t r_{t+1}]\) is the discounted return.

CTDE: We adopt the framework of centralized training and decentralized execution (CTDE, Kraemer & Banerjee, 2016), which assumes access to all action-observation histories \(\tau^a_t\) and global state \(s^a_t\) during training, but each
agent’s decentralized policy \(\pi^a\) can only condition on its own action-observation history \(\tau^a_w\). This approach can exploit information that is not available during execution and also freely share parameters and gradients, which improves the sample efficiency (see e.g., Foerster et al., 2018; Rashid et al., 2020b; Böhmer et al., 2020).

**Value Decomposition Networks:** A naive way to learn in MARL is independent Q-learning (IQL, Tan, 1993), which learns an independent action-value function \(Q^a(\tau^a_w, u^a_w; \theta^a)\) for each agent \(a\) that conditions only on its local action-observation history \(\tau^a_w\). To make better use of other agents’ information in CTDE, value decomposition networks (VDN, Sunehag et al., 2017) represent the joint action value function \(Q_{tot}\) as a sum of per-agent utility functions \(Q^a\): 
\[
Q_{tot}(\tau, u; \theta) = \sum_{a=1}^{n} Q^a(\tau^a_w, u^a_w; \theta).
\]
Each \(Q^a\) still conditions only on individual action-observation histories and can be represented by an agent network that shares parameters across all agents. The joint action-value function \(Q_{tot}\) can be trained using Deep Q-Networks (DQN, Mnih et al., 2015).

Unlike VDN, QMIX (Rashid et al., 2020b) represents the joint action-value function \(Q_{tot}\) with a nonlinear combination of individual utility functions. The greedy joint action in both VDN and QMIX can be computed in a decentralized fashion by individually maximizing each agent’s utility. See OroojlooyJadid & Hajinezhad (2019) for a more in-depth overview of cooperative deep MARL.

**Task-based Universal Value Functions:** In this paper, we consider tasks that differ only in their reward functions \(R_w(s, u) \equiv w^\top \phi(s, u)\), which are linear combinations of a set of basis functions \(\phi : S \times U \rightarrow \mathbb{R}^d\). Intuitively, the basis functions \(\phi\) encode potentially rewarded events, such as opening a door or picking up an object. We use the weight vector \(w\) to denote the task with reward function \(R_w\). Universal Value Functions (UVFs, Schaul et al., 2015) extend DQN to learn a generalizable value function conditioned on tasks. UVFs are typically of the form \(Q^\pi(s_t, u_t, w)\) to indicate the action-value function of task \(w\) under policy \(\pi\) at time \(t\) as:
\[
Q^\pi(s_t, u_t, w) = \mathbb{E}^\pi \left[ \sum_{i=0}^{\infty} \gamma^i R_w(s_{t+i}, u_{t+i}) \mid s_t, u_t \right] \\
= \mathbb{E}^\pi \left[ \sum_{i=0}^{\infty} \gamma^i \phi(s_{t+i}, u_{t+i})^\top w \right] \mid s_t, u_t.
\]  
(1)

**Successor Functions:** The Successor Representation (Dayan, 1993) has been widely used in single-agent settings (Barreto et al., 2017; 2018; Borsa et al., 2018) to generalize across tasks with given reward specifications. By simply rewriting the definition of the action-value function \(Q^\pi(\tau, u, w)\) of task \(w\) from Equation 1 we have:
\[
Q^\pi(\tau, u, w) = \mathbb{E}^\pi \left[ \sum_{i=0}^{\infty} \gamma^i \phi(s_{t+i}, u_{t+i}) \mid s_t, u_t \right]^\top w \\
= \psi^\pi(s_t, u_t)^\top w,\ 
\]  
(2)

where \(\psi^\pi(s, u)\) are the Successor Features (SFs) under policy \(\pi\). For the optimal policy \(\pi^*_z\) of task \(z\), the SFs \(\psi^*_z\) summarize the dynamics under this policy, which can then be weighted with any reward vector \(w \in \mathbb{R}^d\) to instantly evaluate policy \(\pi^*_z\) on it:
\[
Q^\ast_z(s, u, w) = \psi^*_z(s, u)^\top w.
\]

**Universal Successor Features and Generalized Policy Improvement:** Borsa et al. (2018) introduce universal successor features (USFs) that learn SFs conditioned on tasks using the generalization power of UVFs. Specifically, they define UVFs of the form \(Q(s, u, z, w)\) which represents the value function of policy \(\pi_z\) evaluated on task \(w \in \mathbb{R}^d\). These UVFs can be factored using the SFs property (Equation 2) as:
\[
Q(s, u, z, w) = \psi(s, u, z)^\top w, \ 
\]  
where \(\psi(s, u, z)\) are the USFs that generate the SFs induced by task-specific policy \(\pi_z\). One major advantage of using SFs is the ability to efficiently do generalized policy improvement (GPI, Barreto et al., 2017), which allows a new policy to be computed for any unseen task based on instant policy evaluation of a set of policies on that unseen task with a simple dot-product. Formally, given a set \(C \subseteq \mathbb{R}^d\) of tasks and their corresponding SFs \(\{\psi(s, u, z)\}_{z \in C}\) induced by corresponding policies \(\{\pi_z\}_{z \in C}\), a new policy \(\pi'_w\) for any unseen task \(w \in \mathbb{R}^d\) can be derived using:
\[
\pi'_w(s) \in \arg \max_{u \in U} \max_{z \in C} Q(s, u, z, w) \\
\in \arg \max_{u \in U} \max_{z \in C} \psi(s, u, z)^\top w. 
\]  
(3)

Setting \(C = \{w\}\) allows us to revert back to UVFs, as we evaluate SFs induced by policy \(\pi_w\) on task \(w\) itself. However, we can use any set of tasks that are similar to \(w\) based on some similarity distribution \(D(\cdot|w)\). The computed policy \(\pi'_w\) is guaranteed to perform no worse on task \(w\) than each of the policies \(\{\pi_z\}_{z \in C}\) (Barreto et al., 2017), but often performs much better. SFs thus enable efficient use of GPI, which allows reuse of learned knowledge for zero-shot generalization.

4. Multi-Agent Universal Successor Features

In this section, we introduce Multi-Agent Universal Successor Features (MAUSFs), extending single-agent USFs (Borsa et al., 2018) to multi-agent settings and show how we can learn generalized decentralized greedy policies for agents. The USFs based centralized joint action value function \(Q_{tot}(\tau, u, z, w)\) allows evaluation of joint policy \(\pi_z = \langle \pi^1_z, \ldots, \pi^n_z \rangle\) comprised of local agent policies \(\pi^a_z\) of the same task \(z\) on task \(w\). However, each agent \(a\) may execute a different policy \(\pi^a_w\) of different task \(z^a \in C^a\) resulting in a combinatorial set of joint policies. Maximizing over all combinations \(z \equiv (z^1, \ldots, z^n) \in C^n\) should therefore enormously improve GPI. To enable this flexibility, we define the joint action-value function \(Q_{tot}\) of joint policy \(\pi_z = \{\pi^a_w\}_{z^a \in C^n}\) evaluated on any task \(w \in \mathbb{R}^d\) as:
We can now learn local agent-specific SFs \( \psi \) when there are more than a handful of agents, since the joint decentralized execution of a set \( \psi \) summarizing the joint dynamics of the environment under joint policy \( z \). However, training centralized MAUSFs and using centralized GPI to maximize over a combinatorial space of \( z \) becomes impractical when there are more than a handful of agents, since the joint action space \( (U) \) and joint task space \( (C^n) \) of the agents grows exponentially with the number of agents. To leverage CTDE and enable decentralized execution by agents, we therefore propose novel agent-specific SFs for each agent \( a \) following local policy \( \pi^a \), which condition only on its own local action-observation history and task \( z^a \).

Decentralized Execution: We define local utility functions for each agent \( a \) as \( Q^a(\tau^a, u^a, z^a, w) = \psi^a(\tau^a, u^a, z^a; \theta)^T w \), where \( \psi^a(\tau^a, u^a, z^a; \theta) \) are the local agent-specific SFs induced by local policy \( \pi^a_u(u^a|\tau^a) \) of agent \( a \) sharing parameters \( \theta \). Intuitively, \( Q^a(\tau^a, u^a, z^a, w) \) is the utility function for agent \( a \) when local policy \( \pi^a_u(u^a|\tau^a) \) of task \( z^a \) is executed on task \( w \). We use VDN decomposition to represent MAUSFs \( \psi \) as a sum of local agent-specific SFs for each agent \( a \):

\[
Q_{tot}(\tau, u, z, w) = \psi_{tot}(\tau, u, z)^T w,
\]

where \( \psi_{tot}(\tau, u, z) \) are the MAUSFs of \( (\tau, u, z) \) summarizing the joint dynamics of the environment under joint policy \( z \). However, training centralized MAUSFs grows exponentially with the number of agents.

Decentralized GPI: Our novel agent-specific SFs \( \psi^a \) for each agent \( a \) that can be instantly weighted with any task vector \( w \in \mathbb{R}^d \) to generate local utility functions \( Q^a \), thereby allowing agents to use the GPI policy in a decentralized manner.

5. UneVEn

In this section, we present UneVEn (red region of Figure 3), which leverages MAUSFs and decentralized GPI to help
overcome relative overgeneralization on the target task \( w \). At the beginning of every exploration episode, we sample a set of related tasks \( \nu = \{ z \sim D(z | \{w\}) \} \), containing potentially simpler reward functions, from a distribution \( D \) around the target task. The basic idea is that some of these related tasks can be efficiently learned with a factored value function. These tasks are therefore solved early and exploration concentrates on the state-action pairs that are useful to them. If other tasks close to those already solved have the same optimal actions, this implicit weighting allows to solve them too (shown by Rashid et al., 2020a). Furthermore, tasks closer to \( w \) are sampled more frequently, which biases the process to eventually overcome relative overgeneralization on the target task itself.

Our method assumes that the basis functions \( \phi \) and the reward-weights \( w \) of the target task are known, but Barreto et al. (2020) show that both can be learned using multitask regression. Many choices for \( D \) are possible, but in the following we sample related tasks using a normal distribution centered around the target task \( w \in \mathbb{R}^d \) with a small variance \( \sigma \) as \( D = \mathcal{N}(w, \sigma I_d) \). This samples similar tasks closer to \( w \) more frequently. As long as \( \sigma \) is large enough to cover tasks that do not induce RO (see Figure 2), our method works well and therefore, does not rely on any domain knowledge. The resulting task vectors weight the basis functions \( \phi \) differently and represent different reward functions. In particular the varied reward functions can make these tasks much easier, but also harder, to solve with monotonic value functions. The consequences of sampling harder tasks on learning are discussed with the below action-selection schemes.

**Action-Selection Schemes:** UneVEn uses two novel schemes to enable action selection based on related tasks. To emphasize the importance of the target task, we define a probability \( \alpha \) of selecting actions based on the target task. Therefore, with probability \( 1-\alpha \), the action is selected based on the related task. Similar to other exploration schemes, \( \alpha \) is annealed from 0.3 to 1.0 in our experiments over a fixed number of steps at the beginning of training. Once this exploration stage is finished (i.e., \( \alpha = 1 \)), actions are always taken based on the target task’s joint action value function. Each action-selection scheme employs a local decentralized GPI policy, which maximizes over a set of policies \( \pi_z \) based on \( z \in C_1 \) (also referred to as the *evaluation* set) to estimate the \( Q \)-values of another set of tasks \( k \in C_2 \) (also referred to as the *target* set) using:

\[
u_t = \left\{ u_t^a = \arg \max_{u \in \mathcal{U}} \max_{k \in C_2} \max_{z \in \mathcal{C}_1} Q^a(\pi_t^a, u, z, k) \right\}_{a \in \mathcal{A}}.
\]

Here \( \mathcal{C}_1 = \nu \cup \{ w \} \) is the set of target and related tasks that induce the policies that are evaluated (dot-product) on the set of tasks \( C_2 \), which varies with different action-selection schemes. The red box in Figure 3 illustrates UneVEn exploration. For example, Q-learning always picks actions based on the target task, i.e., the target set \( C_2 = \{ w \} \). However, this scheme does not favor important joint actions. We call this default action-selection scheme target GPI and execute it with probability \( \alpha \). We now propose two novel action-selection schemes based on related tasks with probability \( 1 - \alpha \), and thereby implicitly weighting joint actions during learning.

**Uniform GPI:** At the beginning of each episode, this action-selection scheme uniformly picks one related task, i.e., the target set \( C_2 = \nu \cup \{ w \} \), and selects actions based on that task using the GPI policy throughout the episode. This uniform task selection explores the learned policies of all related tasks in \( D \). This works well in practice as there are often enough simpler tasks to induce the required bias over important joint actions. However, if the sampled related task is harder than the target task, the action-selection based on these harder tasks might hurt learning on the target task and lead to higher variance during training.

**Greedy GPI:** At every time-step \( t \), this action-selection scheme picks the task \( k \in \nu \cup \{ w \} \) that gives the highest \( Q \)-value amongst the related and target tasks, i.e., the target set becomes \( C_2 = \nu \cup \{ w \} \). Due to the greedy nature of this action-selection scheme, exploration is biased towards solved tasks, as those have larger values. We are thus exploring the solutions of tasks that are both solvable and similar to the target task \( w \), which should at least in some states lead to the same optimal joint actions as \( w \).

**NO-GPI:** To demonstrate the influence of GPI on the above schemes, we also investigate ablations, where we define the evaluation set \( \mathcal{C}_1 = \{ k \} \) to only contain the currently estimated task \( k \), i.e., using \( u_t = \left\{ u_t^a = \arg \max_{u \in \mathcal{U}} \max_{z \in \mathcal{C}_1} Q^a(\pi_t^a, u, z, k) \right\}_{a \in \mathcal{A}} \) for action selection.

6. Experiments

In this section, we evaluate UneVEn on a variety of complex domains. For evaluation, all experiments are carried out with six random seeds and results are shown with ± standard error across seeds. We compare our method against a number of SOTA value-based MARL approaches: IQL (Tan, 1993), VDN (Sunehag et al., 2017), QMIX (Rashid et al., 2020b), MAVEN (Mahajan et al., 2019), WQMIX (Rashid et al., 2020a), QTRAN (Son et al., 2019), and QPLEX (Wang et al., 2020a).

**Domain 1: m-Step Matrix Game**

We first evaluate UneVEn on the \( m \)-step matrix game proposed by Mahajan et al. (2019). This task is difficult to
solve using simple $\epsilon$-greedy exploration policies as committed exploration is required to achieve the optimal return. Appendix C shows the $m$-step matrix game in which the first joint decision of two agents determines the maximal outcome after another $m - 1$ decisions. One initial joint action can reach a return of up to $m + 3$, whereas another only allows for $m$. This challenges monotonic value functions, as the target task exhibits RO. Figure 4 shows the results of all methods on this task for $m = 10$ after training for $35k$ steps. UneVEn with greedy (UneVEn-Greedy-GPI) action selection scheme converges to an optimal return and both greedy and uniform (UneVEn-Uniform-GPI) schemes outperform all other methods, which suffer from poor $\epsilon$-greedy exploration and often learn to take the suboptimal action in the beginning. Due to RO, it becomes difficult to change the policy later, leading to suboptimal returns and only rarely converging to optimal solutions.

**Domain 2 : Cooperative Predator-Prey**

We next evaluate UneVEn on challenging cooperative predator-prey tasks similar to one proposed by Son et al. (2019), but significantly more complex in terms of the coordination required amongst agents. We use a complex partially observable predator-prey (PP) task involving eight agents (predators) and three prey that is designed to test coordination between agents, as each prey needs to be captured by at least three surrounding agents with a simultaneous capture action. If only one or two surrounding agents attempt to capture the prey, a negative reward of magnitude $p$ is given. Successful capture yields a positive reward of $+1$. More details about the task are available in Appendix C.

**Simpler PP Tasks:** We first demonstrate that both VDN and QMIX with monotonic value functions can learn on target tasks with simpler reward functions. To generate a simpler task, we remove the penalty associated with miscoordination, i.e., $p = 0$, thereby making the target task free from RO. Figure 6 shows that both QMIX and VDN can solve this task as there is no miscoordination penalty and the monotonic value function can learn to efficiently represent the optimal joint action values. Other SOTA value-based approaches (MAVEN, WQMIX, and QPLEX) and UneVEn with both uniform (UneVEn-Uniform-GPI) and greedy (UneVEn-Greedy-GPI) action-selection schemes can solve this target task as well.

**Harder PP Tasks:** We now raise the chance that RO occurs in the target task by increasing the magnitude of the penalty associated with each miscoordination, i.e., $p \in \{0.004, 0.008, 0.012, 0.016\}$. For a smaller penalty of $p = 0.004$, Figure 5 (top left) shows that VDN can still solve the task, further suggesting that simpler reward related tasks (with lower penalties) can be solved with monotonic approximations. However, both QMIX and VDN fail to learn on three other higher penalty target tasks due to their monotonic constraints, which hinder the accurate learning of the joint action value functions. Intuitively, when uncoordinated joint actions are much more likely than coordinated ones, the penalty term can dominate the average value estimated by each agent’s utility. This makes it difficult to learn an accurate monotonic approximation that selects the optimal joint actions.

Interestingly, other SOTA value-based approaches that aim to address the monotonicity restriction of QMIX and VDN such as MAVEN, QTRAN, WQMIX, and QPLEX also fail to learn on higher penalty tasks. WQMIX solves the task when $p = 0.004$, but fails on the other three higher penalty target tasks. Although WQMIX uses an explicit weighting mechanism to bias learning towards the target task’s optimal joint actions, it must identify these actions by learning an unrestricted value function first. An $\epsilon$-greedy exploration based on the target task takes a long time to learn such a value function, which is visible in the large standard error for $p \in \{0.008, 0.012, 0.016\}$ in Figure 5. By contrast, both UneVEn-Uniform-GPI and UneVEn-Greedy-GPI can approximate value functions of target tasks exhibiting severe RO more accurately and solve the task for all values of $p$. As expected, the variance of UneVEn-Uniform-GPI is high on higher penalty target tasks (for e.g., $p = 0.016$) as exploration suffers from action selection based on harder related tasks. UneVEn-Greedy-GPI does not suffer from this problem. Videos of learnt policies are available at https://sites.google.com/view/uneven-marl/.

We emphasize that while having an unrestricted joint value function (such as WQMIX, QPLEX and QTRAN) may allow to overcome RO, these algorithms are not guaranteed to do so in any reasonable amount of time. For example, Rashid et al. (2020a) note in Sec. 6.2.2 that training such a joint function can require much longer $\epsilon$-greedy exploration schedules. The exact optimization of QTRAN is computationally intractable and a lot of recent work has shown the unstable performance of the corresponding approximate versions. Similarly QPLEX has shown to perform poorly on hard SMAC maps in our results and in Rashid et al. (2020a).

On the other hand, MAVEN learns a diverse ensemble of

Figure 4. SOTA comparison on the $m$-step matrix game ($m = 10$).
monotonic action-value functions, but does not concentrate on joint actions that would overcome RO if explored more.

**Ablations:** Figure 7 shows ablation results for higher penalty tasks, i.e., $p = \{0.012, 0.016\}$. To contrast the effect of UneVEn on exploration, we compare our two novel action-selection schemes to UneVEn-Target-GPI, which only selects the greedy actions of the target task. The results clearly show that UneVEn-Target-GPI fails to solve the higher penalty RO tasks as the employed monotonic joint value function of the target task fails to accurately represent the values of different joint actions. This demonstrates the critical role of UneVEn and its action-selection schemes. Next we evaluate the effect of GPI by comparing against UneVEn with MAUSFs without using the GPI policy, i.e., setting the evaluation set $C_1 = \{k\}$ in Equation 7. First, UneVEn using a NOGPI policy with both uniform (Uniform-NOGPI) and greedy (Greedy-NOGPI) action selection outperforms Target-NOGPI, further strengthening the claim that UneVEn with its novel action-selection scheme enables efficient exploration and bias towards optimal joint actions. In addition, the left and middle plots of Figure 7 shows that for each corresponding action-selection scheme (uniform, greedy, and target), using a GPI policy ($\ast$-GPI) is consistently favourable as it performs either similarly to the NOGPI policy ($\ast$-NOGPI) or much better. GPI appears to improve zero-shot generalization of MAUSFs across tasks, which in turn enables good action selection for related tasks during UneVEn exploration.

**Zero-Shot Generalization:** Lastly, we evaluate this zero-shot generalization for all methods to check if the learnt policies are useful for unseen high penalty test tasks. We train all methods for 8 million environmental steps on a task with $p = 0.004$, and test 60 rollouts of the resulting policies of all methods that are able to solve the training task, i.e., UneVEn-Greedy-GPI, UneVEn-Uniform-GPI, VDN, MAVEN, and WQMIX, on tasks with $p \in \{0.2, 0.5\}$. For policies trained with UneVEn-Greedy-GPI and UneVEn-Uniform-GPI, we use the NOGPI policy for the zero-shot testing, i.e., $C_1 = C_2 = \{w\}$. The right plot of Figure 7 shows that UneVEn with both uniform and greedy schemes exhibits great zero-shot generalization and solves both test tasks even with very high penalties. As MAUSFs learn the reward’s basis functions, rather than the reward itself, zero-shot generalization to larger penalties follows naturally. Furthermore, using UneVEn exploration allows the agents to collect enough diverse behaviour to come up with a near optimal policy for the test tasks. On the other hand, the
learnt policies for all other methods that solve the target

Improving monotonic value function factorization in

CTDE: MAVEN (Mahajan et al., 2019) shows that the
monotonic joint action value function of QMIX and VDN
suffers from suboptimal approximations on nonmonotonic
tasks. It addresses this problem by learning a diverse ensem-
ble of monotonic joint action-value functions conditioned
on a latent variable by optimizing the mutual information
between the joint trajectory and the latent variable. Deep
Coordination Graphs (DCG) (Böhmer et al., 2020) uses
a predefined coordination graph (Guestrin et al., 2002) to
represent the joint action value function. However, DCG
is not a fully decentralized approach and specifying the
coordination graph can require significant domain knowl-
edge. Son et al. (2019) propose QTRAN, which addresses
the monotonic restriction of QMIX by learning a (decentralizable) VDN-factored joint action value function along with an unrestricted centralized critic. The corresponding utility functions are distilled from the critic by solving a linear optimization problem involving all joint actions, but its exact implementation is computationally intractable and the corresponding approximate versions have unstable performance. TESSERACT (Mahajan et al., 2021) proposes a tensor decomposition based method for learning arbitrary action-value functions, they also provide sample complexity analysis for their method. QPLEX (Wang et al., 2020a) uses a duplex dueling (Wang et al., 2016) network architecture to factorize the joint action value function with linear decomposition structure. WQMIX (Rashid et al., 2020a) learns a QMIX-factored joint action value function along with an unrestricted centralized critic and proposes explicit weighting mechanisms to bias the monotonic approximation of the optimal joint action value function towards important joint actions, which is similar to our work. However, in our work, the weightings are implicitly done through action-selection based on related tasks, which are easier to solve.

**Exploration:** There are many techniques for exploration in model-free single-agent RL, based on intrinsic novelty reward (Bellemare et al., 2016; Tang et al., 2017), predictability (Pathak et al., 2017), pure curiosity (Burda et al., 2019) or Bayesian posteriors (Osband et al., 2016; Gal et al., 2017; Fortunato et al., 2018; O’Donoghue et al., 2018). In the context of multi-agent RL, Böhmer et al. (2019) discuss the influence of unreliable intrinsic reward and Wang et al. (2020c) quantify the influence that agents have on each other’s return. Similarly, Wang et al. (2020b) propose a learnable action effect based role decomposition which eases exploration in the joint action space. Zheng & Yue (2018) propose to coordinate exploration between agents by shared latent variables, whereas Jaques et al. (2018) investigate the social motivations of competitive agents. However, these techniques aim to visit as much of the state-action space as possible, which exacerbates the relative overgeneralization pathology. Approaches that use state-action space abstraction can speed up exploration, these include those which can automatically learn the abstractions (e.g., Mahajan & Tulabandhula, 2017a;b) and those which require prior knowledge (e.g., Roderick et al., 2018), however they are difficult to scale for multi-agent scenarios. In contrast, UneVEn explores similar tasks. This guides exploration to states and actions that prove useful, which restricts the explored space and overcomes relative overgeneralization. To the best of our knowledge, the only other work that explores the task space is Leibo et al. (2019): they use the evolution of competing agents as an auto-curriculum of harder and harder tasks. Collaborative agents cannot compete against each other, though, and their approach therefore is not suitable to learn cooperation.

**Successor Features:** Most of the work on SFs have been focused on single-agent settings (Dayan, 1993; Kulkarni et al., 2016; Lehnert et al., 2017; Barreto et al., 2017; 2018; Borsa et al., 2018; Lee et al., 2019; Hansen et al., 2019) for transfer learning and zero-shot generalization across tasks with different reward functions. Gupta et al. (2019) use single-agent SFs in a multi-agent setting to estimate the probability of events, but they only consider transition independent MARL (Becker et al., 2004; Gupta et al., 2018).

**8. Conclusion**

This paper presents a novel approach decomposing multi-agent universal successor features (MAUSFs) into local agent-specific SFs, which enable a decentralized version of the GPI to maximize over a combinatorial space of agent policies. We propose UneVEn, which leverages the generalization power of MAUSFs to perform action selection based on simpler related tasks to address the suboptimality of the target task’s monotonic joint action value function in current SOTA methods. Our experiments show that UneVEn significantly outperforms VDN, QMIX and other state-of-the-art value-based MARL methods on challenging tasks exhibiting severe RO.

**9. Future Work**

UneVEn relies on the assumption that both the basis functions and the reward-weights of the target task are known which restricts the applicability of the method. Moreover, our SFs based method requires learning in $d$ dimensions instead of learning scalar values for each action in the case of $Q$-learning, which decreases the scalability of our method for domains where $d$ is very large. More efficient neural network architectures with hyper networks (Ha et al., 2016) can be leveraged to handle larger dimensional features. Finally, the paradigm of UneVEn with related task based action selection can be directly applied with universal value functions (UVFs) (Schaul et al., 2015) to enable other state-of-the-art nonlinear mixing techniques like QMIX (Rashid et al., 2020b) and QPLEX (Wang et al., 2020a) to overcome RO, at the cost of losing ability to perform GPI.
