Abstract

The deadly triad refers to the instability of a reinforcement learning algorithm when it employs off-policy learning, function approximation, and bootstrapping simultaneously. In this paper, we investigate the target network as a tool for breaking the deadly triad, providing theoretical support for the conventional wisdom that a target network stabilizes training. We first propose and analyze a novel target network update rule which augments the commonly used Polyak-averaging style update with two projections. We then apply the target network and ridge regularization in several divergent algorithms and show their convergence to regularized TD fixed points. Those algorithms are off-policy with linear function approximation and bootstrapping, spanning both policy evaluation and control, as well as both discounted and average-reward settings. In particular, we provide the first convergent linear Q-learning algorithms under nonrestrictive and changing behavior policies without bi-level optimization.

1. Introduction

The deadly triad (see, e.g., Chapter 11.3 of Sutton & Barto (2018)) refers to the instability of a value-based reinforcement learning (RL, Sutton & Barto (2018)) algorithm when it employs off-policy learning, function approximation, and bootstrapping simultaneously. Different from on-policy methods, where the policy of interest is executed for data collection, off-policy methods execute a different policy for data collection, which is usually safer (Dulac-Arnold et al., 2019) and more data efficient (Lin, 1992; Sutton et al., 2011). Function approximation methods use parameterized functions, instead of a look-up table, to represent quantities of interest, which usually cope better with large-scale problems (Mnih et al., 2015; Silver et al., 2016). Bootstrapping methods construct update targets for an estimate by using the estimate itself recursively, which usually has lower variance than Monte Carlo methods (Sutton, 1988). However, when an algorithm employs all those three preferred ingredients (off-policy learning, function approximation, and bootstrapping) simultaneously, there is usually no guarantee that the resulting algorithm is well behaved and the value estimates can easily diverge (see, e.g., Baird (1995); Tsitsiklis & Van Roy (1997); Zhang et al. (2021)), yielding the notorious deadly triad.

An example of the deadly triad is Q-learning (Watkins & Dayan, 1992) with linear function approximation, whose divergence is well documented in Baird (1995). However, Deep-Q-Networks (DQN, Mnih et al. (2015)), a combination of Q-learning and deep neural network function approximation, has enjoyed great empirical success. One major improvement of DQN over linear Q-learning is the use of a target network, a copy of the neural network function approximator (the main network) that is periodically synchronized with the main network. Importantly, the bootstrapping target in DQN is computed via the target network instead of the main network. As the target network changes slowly, it provides a stable bootstrapping target which in turn stabilizes the training of DQN. Instead of the periodical synchronization, Lillicrap et al. (2015) propose a Polyak-averaging style target network update, which has also enjoyed great empirical success (Fujimoto et al., 2018; Haarnoja et al., 2018).

Inspired by the empirical success of the target network in RL with deep networks, in this paper, we theoretically investigate the target network as a tool for breaking the deadly triad. We consider a two-timescale framework, where the main network is updated faster than the target network. By using a target network to construct the bootstrapping target, the main network update becomes least squares regression. After adding ridge regularization (Tikhonov et al., 2013) to this least squares problem, we show convergence for both the target and main networks.

Our main contributions are twofold. First, we propose a novel target network update rule augmenting the Polyak-averaging style update with two projections. The balls for the projections are usually large so most times they are just identity mapping. However, those two projections offer sig-
significant theoretical advantages making it possible to analyze where the target network converges to (Section 3). Second, we apply the target network in various existing divergent algorithms and show their convergence to regularized TD (Sutton, 1988) fixed points. Those algorithms are off-policy algorithms with linear function approximation and bootstrapping, spanning both policy evaluation and control, as well as both discounted and average-reward settings. In particular, we provide the first convergent linear Q-learning algorithms under nonrestrictive and changing behavior policies without bi-level optimization, for both discounted and average-reward settings.

2. Background

Let \( M \) be a real positive definite matrix and \( x \) be a vector, we use \( \|x\|_M = \sqrt{x^\top M x} \) to denote the norm induced by \( M \) and \( \|\cdot\|_{M^p} \) to denote the corresponding induced matrix norm. When \( M \) is the identity matrix \( I \), we ignore the subscript \( I \) for simplicity. We use vectors and functions interchangeably when it does not cause confusion, e.g., given \( f : X \to \mathbb{R} \), we also use \( f \) to denote the corresponding vector in \( \mathbb{R}^{|X|} \). All vectors are column vectors. We use \( \mathbf{1} \) to denote an all one vector, whose dimension can be deduced from the context. \( \mathbf{0} \) is similarly defined.

We consider an infinite horizon Markov Decision Process (MDP, see, e.g., Puterman (2014)) consisting of a finite state space \( S \), a finite action space \( \mathcal{A} \), a transition kernel \( p : S \times S \times \mathcal{A} \to [0,1] \), and a reward function \( r : S \times \mathcal{A} \to \mathbb{R} \). At each state \( t \), an agent at state \( S_t \) executes an action \( A_t \sim \pi(\cdot|S_t) \), where \( \pi : \mathcal{A} \times S \to [0,1] \) is the policy followed by the agent. The agent then receives a reward \( R_{t+1} = r(S_t, A_t) \) and proceeds to a new state \( S_{t+1} \sim p(\cdot|S_t, A_t) \).

In the discounted setting, we consider a discount factor \( \gamma \in [0,1) \) and define the return at time step \( t \) as \( G_t = \sum_{i=0}^{\infty} \gamma^t R_{t+i} \), which allows us to define the action-value function \( q_\pi(s,a) = \mathbb{E}_{\pi,p}[G_t|S_t = s, A_t = a] \). The action-value function \( q_\pi \) is the unique fixed point of the Bellman operator \( T_\pi \), i.e., \( q_\pi = T_\pi q_\pi = r + \gamma P_\pi q_\pi \), where \( P_\pi \in \mathbb{R}^{|S||A| \times |S||A|} \) is the transition matrix, i.e., \( P_\pi((s,a),(s',a')) = \sum_a p(s'|s,a) \pi(a'|s') \).

In the average-reward setting, we assume:

**Assumption 2.1.** The chain induced by \( \pi \) is ergodic.

This allows us to define the reward rate \( \bar{r}_\pi = \lim_{T \to \infty} \frac{1}{T} \sum_{t=1}^{T} \mathbb{E}[R_t|p, \pi] \). The differential action-value function \( \bar{q}_\pi(s) \) is defined as:

\[
\lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T} \mathbb{E}_{\pi,p}[r(S_t, A_t) - \bar{r}_\pi|S_0 = s, A_0 = a].
\]

The differential Bellman equation is

\[
\bar{q} = r - \bar{r}\mathbf{1} + P_\pi \bar{q},
\]

where \( \bar{q} \in \mathbb{R}^{|S||A|} \) and \( \bar{r} \in \mathbb{R} \) are free variables. It is well known that all solutions to (1) form a set \( \{(\bar{q}, \bar{r})| \bar{r} = \bar{r}_\pi, \bar{q} = q_\pi + c\mathbf{1}, c \in \mathbb{R}\} \) (Puterman, 2014).

The policy evaluation problem refers to estimating \( q_\pi \) or \( (\bar{q}_\pi, \bar{r}_\pi) \). The control problem refers to finding a policy \( \pi \) maximizing \( q_\pi(s,a) \) for each \((s,a)\) or maximizing \( \bar{r}_\pi \). With linear function approximation, we approximate \( q_\pi(s,a) \) or \( \bar{q}_\pi(s,a) \) with \( x(s,a)^\top w \), where \( x : S \times \mathcal{A} \to \mathbb{R}^K \) is a feature mapping and \( w \in \mathbb{R}^K \) is the learnable parameter. We use \( X \in \mathbb{R}^{|S||A| \times K} \) to denote the feature matrix, each row of which is \( x(s,a)^\top \), and assume:

**Assumption 2.2.** \( X \) has linearly independent columns.

In the average-reward setting, we use an additional parameter \( \bar{r} \in \mathbb{R} \) to approximate \( \bar{r}_\pi \). In the off-policy learning setting, the data for policy evaluation or control is collected by executing a policy \( \mu \) (behavior policy) in the MDP, which is different from \( \pi \) (target policy). In the rest of the paper, we consider the off-policy linear function approximation setting thus always assume \( \bar{r} \sim \mu(|S_0|) \). We use as shorthand \( x_t = x(S_t, A_t), \bar{x}_t = \sum_a \pi(a|S_t)x(S_t, a) \).

**Policy Evaluation.** In the discounted setting, similar to Temporal Difference Learning (TD, Sutton (1988)), one can use Off-Policy Expected SARSA to estimate \( q_\pi \), which updates \( w \) as

\[
\delta_t \leftarrow R_{t+1} + \gamma \bar{x}_{t+1} - x_t^\top w_t,
\]

\[
w_{t+1} \leftarrow w_t + \alpha_t \delta_t x_t,
\]

where \( \{\alpha_t\} \) are learning rates. In the average-reward setting, (1) implies that \( \bar{r}_\pi = d^\top (r + P_\pi \bar{q}_\pi - \bar{q}_\pi) \) holds for any probability distribution \( d \). In particular, it holds for \( d = d_\mu \). Consequently, to estimate \( q_\pi \) and \( \bar{r}_\pi \), Wan et al. (2020); Zhang et al. (2021) update \( w \) and \( \bar{r} \) as

\[
w_{t+1} \leftarrow w_t + \alpha_t (R_{t+1} - \bar{r}_t + x_t^\top w_t - x_{t+1}^\top w_{t+1}) x_t,
\]

\[
\bar{r}_{t+1} \leftarrow \bar{r}_t + \alpha_t (R_{t+1} - x_t^\top w_t - x_{t+1}^\top w_{t+1}).
\]

Unfortunately, both (2) and (3) can possibly diverge (see, e.g., Tsitsiklis & Van Roy (1997); Zhang et al. (2021)), which exemplifies the deadly triad in discounted and average-reward settings respectively.

**Control.** In the discounted setting, Q-learning with linear function approximation yields

\[
\delta_t \leftarrow R_{t+1} + \gamma \max_{a'} x(S_{t+1}, a')^\top w_t - x_t^\top w_t,
\]

\[
w_{t+1} \leftarrow w_t + \alpha_t \delta_t x_t.
\]

In the average-reward setting, Differential Q-learning (Wan et al., 2020) with linear function approximation yields

\[
\delta_t \leftarrow R_{t+1} - \bar{r}_t + \gamma \max_{a'} x(S_{t+1}, a')^\top w_t - x_t^\top w_t,
\]

\[
w_{t+1} \leftarrow w_t + \alpha_t \delta_t x_t,
\]

\[
\bar{r}_{t+1} \leftarrow \bar{r}_t + \alpha_t \delta_t.
\]
Unfortunately, both (4) and (5) can possibly diverge as well (see, e.g., Baird (1995); Zhang et al. (2021)), exemplifying the deadly triad again.

Motivated by the empirical success of the target network in deep RL, one can apply the target network in the linear function approximation setting. For example, using a target network in (4) yields

\[ w_{t+1} \leftarrow w_t + \alpha_t \Delta_t x_t, \]  
(6) \[
\theta_{t+1} \leftarrow \theta_t + \beta_t (w_t - \theta_t), \] 
(7)

where \( \theta \) denotes the target network, \( \{ \beta_t \} \) are learning rates, and we consider the Polyak-averaging style target network update. The convergence of (6) and (7), however, remains unknown. Besides target networks, regularization has also been widely used in deep RL, e.g., Mnih et al. (2015) consider a Huber loss instead of a mean-squared loss; Lillicrap et al. (2015) consider \( \ell_2 \) weight decay in updating Q-values.

### 3. Analysis of the Target Network

In Sections 4 & 5, we consider the merits of using a target network in several linear RL algorithms (e.g., (2) (3) (4) (5)). To this end, in this section, we start by proposing and analyzing a novel target network update rule:

\[ \theta_{t+1} \preceq \Gamma_{B_1}(\theta_t + \beta_t (\Gamma_{B_2}(w_t) - \theta_t)). \]  
(8)

In (8), \( w \) denotes the main network and \( \theta \) denotes the target network. \( \Gamma_{B_1} : \mathbb{R}^K \to \mathbb{R}^K \) is a projection to the ball \( B_1 = \{ x \in \mathbb{R}^K \mid \| x \| \leq R_{B_1} \} \), i.e.,

\[ \Gamma_{B_1}(x) \triangleq x_{\| x \| \leq R_{B_1}} + (R_{B_1} x / \| x \|) 1_{\| x \| > R_{B_1}}, \]

where \( I \) is the indicator function. \( \Gamma_{B_2} \) is a projection onto the ball \( B_2 \) with a radius \( R_{B_2} \). We make the following assumption about the learning rates:

**Assumption 3.1.** \( \{ \beta_t \} \) is a deterministic positive non-increasing sequence satisfying \( \sum_t \beta_t = \infty \), \( \sum_t \beta_t^2 < \infty \).

While (8) specifies how \( \theta \) is updated, we assume \( w \) is updated such that \( w \) can track \( \theta \) in the sense that

**Assumption 3.2.** There exists \( w^* : \mathbb{R}^K \to \mathbb{R}^K \) such that

\[ \lim_{t \to \infty} \| w_t - w^*(\theta_t) \| = 0 \text{ almost surely.} \]

After making some additional assumptions on \( w^* \), we arrive at our general convergent results.

**Assumption 3.3.** \( \sup \theta \| w^*(\theta) \| < R_{B_2} < R_{B_1} < \infty \).

**Assumption 3.4.** \( w^* \) is a contraction mapping w.r.t. \( \| \cdot \| \).

**Theorem 1. (Convergence of Target Network)** Under Assumptions 3.1-3.4, the iterate \( \{ \theta_t \} \) generated by (8) satisfies

\[ \lim_{t \to \infty} w_t = \lim_{t \to \infty} \theta_t = \theta^* \text{ almost surely,} \]

where \( \theta^* \) is the unique fixed point of \( w^*(\cdot) \).

Assumptions 3.2 - 3.4 are assumed only for now. Once the concrete update rules for \( w \) are specified in the algorithms in Sections 4 & 5, we will prove that those assumptions indeed hold. Assumption 3.2 is expected to hold because we will later require that the target network to be updated much slower than the main network. Consequently, the update of the main network will become a standard least-square regression, whose solution \( w^* \) usually exists. Assumption 3.4 is expected to hold because we will later apply ridge regularization to the least-square regression. Consequently, its solution \( w^* \) will not change too fast w.r.t. the change of the regression target.

The target network update (8) is the same as that in (7) except for the two projections, where the first projection \( \Gamma_{B_1} \) is standard in optimization literature. The second projection \( \Gamma_{B_2} \), however, appears novel and plays a crucial role in our analysis. **First**, if we have only \( \Gamma_{B_1} \), the iterate \( \{ \beta_t \} \) would converge to the invariant set of the ODE

\[ \frac{d}{dt} \theta(t) = w^*(\theta(t)) - \theta(t) + \zeta(t), \] 
(9)

where \( \zeta(t) \) is a reflection term that moves \( \theta(t) \) back to \( B_1 \) when \( \theta(t) \) becomes too large (see, e.g., Section 5 of Kushner & Yin (2003)). Due to this reflection term, it is possible that \( \theta(t) \) visits the boundary of \( B_1 \) infinitely often. It thus becomes unclear what the invariant set of (9) is even if \( w^* \) is contractive. By introducing the second projection \( \Gamma_{B_2} \) and ensuring \( R_{B_1} > R_{B_2} \), we are able to remove the reflection term and show that the iterate \( \{ \beta_t \} \) tracks the ODE

\[ \frac{d}{dt} \theta(t) = w^*(\theta(t)) - \theta(t), \] 
(10)

whose invariant set is a singleton \( \{ \theta^* \} \) when Assumption 3.4 holds. See the proof of Theorem 1 in Section A.1 based on the ODE approach (Kushner & Yin, 2003; Borkar, 2009) for more details. **Second**, to ensure the main network tracks the target network in the sense of Assumption 3.2 in our applications in Sections 4 & 5, it is crucial that the target network changes sufficiently slowly in the following sense:

**Lemma 1.** \( \| \theta_{t+1} - \theta_t \| \leq \beta_t C_0 \) for some constant \( C_0 > 0 \).

Lemma 1 would not be feasible without the second projection \( \Gamma_{B_2} \) and we defer its proof to Section A.2.

In Sections 4 & 5, we provide several applications of Theorem 1 in both discounted and average-reward settings, for both policy evaluation and control. We consider a two-timescale framework, where the target network is updated more slowly than the main network. Let \( \{ \alpha_t \} \) be the learning rates for updating the main network \( w \); we assume

**Assumption 3.5.** \( \{ \alpha_t \} \) is a deterministic positive non-increasing sequence satisfying \( \sum_t \alpha_t = \infty \), \( \sum_t \alpha_t^2 < \infty \). Further, for some \( d > 0 \), \( \sum_t (\beta_t / \alpha_t)^d < \infty \).
4. Application to Off-Policy Policy Evaluation

In this paper, we consider estimating the action-value \( q_x \) instead of the state-value \( v_x \) for unifying notations of policy evaluation and control. The algorithms for estimating \( v_x \) are straightforward up to change of notations and introduction of importance sampling ratios.

**Discounted Setting.** Using a target network for bootstrapping in (2) yields

\[
    w_{t+1} = w_t + \alpha_t (R_{t+1} + \gamma \tilde{x}^T_{t+1} \theta_t - x^T_t w_t)x_t.
\]

As \( \theta_t \) is quasi-static for \( w_t \) (Lemma 1 and Assumption 3.5), this update becomes least squares regression. Motivated by the success of ridge regularization in least squares and the widespread use of weight decay in deep RL, which is essentially ridge regularization, we add ridge regularization to this least squares, yielding Q-evaluation with a Target Network (Algorithm 1).

**Algorithm 1** Q-evaluation with a Target Network

**INPUT:** \( \eta > 0, R_{B_t} > R_{B_2} > 0 \)

- Initialize \( \theta_0 \in B_1 \) and \( S_0 \)
- Sample \( A_0 \sim \mu(\cdot|S_0) \)

**for** \( t = 0, 1, \ldots \) **do**

- Execute \( A_t \), get \( R_{t+1} \) and \( S_{t+1} \)
- Sample \( A_{t+1} \sim \mu(\cdot|S_{t+1}) \)
- \( \tilde{x}_{t+1} \stackrel{\text{iid}}{\sim} \pi(a'|S_{t+1})x(S_{t+1}, a') \)
- \( \delta_t = R_{t+1} - \theta_t^T \tilde{x}_{t+1} - x^T_t w_t \)
- \( w_{t+1} = w_t + \alpha_t \delta_t x_t - \alpha_t \eta w_t \)
- \( \theta_{t+1} = \Gamma_{B_1}(\theta_t + \beta_t(\Gamma_{B_2}(w_t - \theta_t)) \)

**end for**

Let \( A = X^T D_p (I - \gamma P_r) X, b = X^T D_p r \), where \( D_p \) is a diagonal matrix whose diagonal entry is \( d_p \), the stationary state-action distribution of the chain induced by \( \mu \). Let \( \Pi_{D_p} = X (X^T D_p X)^{-1} X^T D_p \) be the projection to the column space of \( X \). We have

**Assumption 4.1.** The chain in \( S \times A \) induced by \( \mu \) is ergodic.

**Theorem 2.** Under Assumptions 2.2, 3.1, 3.5, & 4.1, for any \( \xi \in (0, 1) \), let \( C_0 \geq \frac{\sigma^2}{\gamma R_{D_p}} \), \( C_1 = \frac{\|X\|}{2 \sqrt{\eta}} + 1 \), then for all \( \|X\| < C_0, C_1 < R_{B_1}, R_{B_2} - \xi < R_{B_3} < R_{B_1} \), the iterate \( \{w_t\} \) generated by Algorithm 1 satisfies

\[
    \lim_{t \to \infty} w_t = w^*_0 \quad \text{almost surely,}
\]

where \( w^*_0 \) is the unique solution of \((A + \eta I)w = b, 0\), and

\[
    \frac{\|X w^*_0 - q_\pi\|}{\|X\|} \leq (\sigma_{\max}(X)^2 \sigma_{\min}(D_p))^{-1/2} \eta \pi + \|\Pi_{D_p} q_\pi - q_\pi\| / \xi,
\]

where \( \sigma_{\max}(\cdot), \sigma_{\min}(\cdot) \) denotes the largest and minimum singular values.

We defer the proof to Section A.3. Theorem 2 requires that the balls for projection are sufficiently large, which is completely feasible in practice. Theorem 2 also requires that the feature norm \( \|X\| \) is not too large. Similar assumptions on feature norms also appear in Zou et al. (2019); Du et al. (2019); Chen et al. (2019b); Carvalho et al. (2020); Wang & Zou (2020); Wu et al. (2020) and can be easily achieved by scaling.

The solutions to \( Aw - b = 0 \), if they exist, are TD fixed points for off-policy policy evaluation in the discounted setting (Sutton et al., 2009b:a). Theorem 2 shows that Algorithm 1 finds a regularized TD fixed point \( w^*_0 \), which is also the solution of Least-Squares TD methods (LSTD, Boyan (1999); Yu (2010)). LSTD maintains estimates for \( A \) and \( b \) (referred to as \( \hat{A} \) and \( \hat{b} \)) in an online fashion, which requires \( O(K^2) \) computational and memory complexity per step. As \( \hat{A} \) is not guaranteed to be invertible, LSTD usually uses \((A + \eta I)^{-1} \hat{b}\) as the solution and \( \eta \) plays a key role in its performance (see, e.g. Chapter 9.8 of Sutton & Barto (2018)). By contrast, Algorithm 1 finds the LSTD solution (i.e., \( w^*_0 \)) with only \( O(K) \) computational and memory complexity per step. Moreover, Theorem 2 provides a performance bound for \( w^*_0 \). Let \( w^*_0 - \beta^* - b \); Koller (2011) shows with a counterexample that the approximation error of TD fixed points (i.e., \( \|X w^*_0 - q_\pi\| \)) can be arbitrarily large if \( \mu \) is far from \( \pi \), as long as there is representation error (i.e., \( \|\Pi_{D_p} q_\pi - q_\pi\| > 0 \) (see Section 6 for details). By contrast, Theorem 2 guarantees that \( \|X w^*_0 - q_\pi\| \) is bounded from above, which is one possible advantage of regularized TD fixed points.

**Algorithm 2** Diff. Q-evaluation with a Target Network

**INPUT:** \( \eta > 0, R_{B_1} > R_{B_2} > 0 \)

- Initialize \( \{\theta^*_0, \theta^*_w\} \in B_1 \) and \( S_0 \)
- Sample \( A_0 \sim \mu(\cdot|S_0) \)

**for** \( t = 0, 1, \ldots \) **do**

- Execute \( A_t \), get \( R_{t+1} \) and \( S_{t+1} \)
- Sample \( A_{t+1} \sim \mu(\cdot|S_{t+1}) \)
- \( \tilde{x}_{t+1} \stackrel{\text{iid}}{\sim} \pi(a'|S_{t+1})x(S_{t+1}, a') \)
- \( \delta_{t+1} = R_{t+1} - \beta^*_t + \tilde{x}_{t+1}^T \theta^*_w - x^T_t w_t \)
- \( w_{t+1} = w_t + \alpha_t \delta_{t+1} x_t - \alpha_t \eta w_t \)
- \( \theta_{t+1} = \Gamma_{B_1}(\theta_t + \beta_t(\Gamma_{B_2}(w_t - \theta_t)) \)

**end for**

**Average-reward Setting.** In the average-reward setting, we need to learn both \( \bar{r} \) and \( w \). Hence, we consider target networks \( \theta^* \) and \( \theta^w \) for \( \bar{r} \) and \( w \) respectively. Plugging \( \theta^* \) and \( \theta^w \) into (3) for bootstrapping yields Differential Q-evaluation with a Target Network (Algorithm 2), where \( \{B_1\} \) are now balls in \( \mathbb{R}^{K+1} \). In Algorithm 2, we impose ridge regularization only on \( w \) as \( \bar{r} \) is a scalar and thus does
Theorem 3. Under Assumptions 2.1, 2.2, 3.1, 3.5, & 4.1, for any \( \xi \in (0,1) \), there exist constants \( C_0 \) and \( C_1 \) such that for all \( \|X\| < C_0, C_1 < R_{B_1}, R_{B_2} - \xi < R_{B_3} < R_{B_4}, \) the iterates \( \{\bar{r}_t\} \) and \( \{w_t\} \) generated by Algorithm 2 satisfy

\[
\lim_{t \to \infty} \bar{r}_t = d^\top_{\mu}(r + P_{\pi}Xw^*_\eta - Xw^*_\eta), \\
\lim_{t \to \infty} w_t = w^*_\eta \quad \text{almost surely,}
\]

where \( w^*_\eta \) is the unique solution of \( (\bar{A} + \eta I)w - \bar{b} = 0 \) with

\[
\bar{A} = X(D_{\mu} - d_{\mu}d_{\mu}^\top)(I - P_{\pi})X, \\
\bar{b} = X^\top(D_{\mu} - d_{\mu}d_{\mu}^\top)r.
\]

If features are zero-centered (i.e., \( X^\top d_{\mu} = 0 \)), then

\[
\|Xw^*_\eta - \bar{q}_c\| \leq (\frac{\sigma_{\max}(X)^2}{\sigma_{\min}(X)^2})\|q_c\|\eta \\
+ \|\Pi_{d_{\mu}}q_c - \bar{q}_c\| \cdot \xi, \\
|\bar{r}^*_\eta - \bar{r}_{\pi}| \leq \|d_{\mu}(P_{\pi} - I)\| \max_i \|X(w^*_\eta - \bar{q}_c)\|,
\]

where \( \bar{q}_c = \bar{q}_{\pi} + cI \).

We defer the proof to Section A.4. As the differential Bellman equation (1) has infinitely many solutions for \( \bar{q} \), all of which differ only by some constant offsets, we focus on analyzing the quality of \( Xw^*_\eta \) w.r.t. \( \bar{q}_c \) in Theorem 3. The zero-centered feature assumption is also used in Zhang et al. (2021), which can be easily fulfilled in practice by subtracting all features with the estimated mean. In the on-policy case (i.e., \( \mu = \pi \)), we have \( d_{\mu}(P_{\pi} - I) = 0 \), indicating \( \bar{r}^*_\eta = \bar{r}_{\pi} \), i.e., the regularization on the value estimate does not pose any bias on the reward rate estimate.

As shown by Zhang et al. (2021), if the update (3) converges, it converges to \( w^*_\eta \), the TD fixed point for off-policy policy evaluation in the average-reward setting, which satisfies \( \bar{A}w^*_\eta + \bar{b} = 0 \). Theorem 3 shows that Algorithm 2 converges to a regularized TD fixed point. Though Zhang et al. (2021) give a bound on \( \|Xw^*_\eta - \bar{q}_c\| \), their bound holds only if \( \mu \) is sufficiently close to \( \pi \). By contrast, our bound on \( w^*_\eta \) in Theorem 3 holds for all \( \mu \).

5. Application to Off-Policy Control

Discounted Setting. Introducing a target network and ridge regularization in (4) yields Q-learning with a Target Network (Algorithm 3), where the behavior policy \( \mu_0 \) depends on \( \theta \) through the action-value estimate \( X\theta \) and can be any policy satisfying the following two assumptions.

Assumption 5.1. Let \( \mathcal{P} \) be the closure of \( \{P_{\mu_0} \mid \theta \in \mathbb{R}^K\} \). For any \( P \in \mathcal{P} \), the Markov chain evolving in \( S \times A \) induced by \( P \) is ergodic.

Assumption 5.2. \( \mu_0(a|s) \) is Lipschitz continuous in \( \theta \).

Algorithm 3 Q-learning with a Target Network

**INPUT:** \( \eta > 0, R_{B_1} > R_{B_2} > 0 \)

Initialize \( \theta_0 \in B_1 \) and \( S_0 \)

Sample \( A_0 \sim \mu_{\theta_0}(|S_0) \)

for \( t = 0, 1, \ldots \) do

- Execute \( A_t \), get \( R_{t+1} \) and \( S_{t+1} \)
- Sample \( A_{t+1} \sim \mu_{\theta_t}(|S_t) \)
- \( \delta_t = R_{t+1} + \gamma \max_{a'} x(S_{t+1}, a')^\top \theta_t - x_t^\top w_t \)
- \( w_{t+1} = w_t + \alpha_t \delta_t x_t - \alpha_t \gamma w_t \)
- \( \theta_{t+1} = \Gamma_{B_1}(\theta_t + \beta_t(\Gamma_{B_2}(w_t) - \theta_t)) \)

end for

Theorem 4. Under Assumptions 2.2, 3.1, 3.5, 5.1, & 5.2, for any \( \xi \in (0,1), R_{B_1} > R_{B_2} > R_{B_3} - \xi > 0 \), there exists a constant \( C_0 \) such that for all \( \|X\| < C_0 \), the iterate \( \{w_t\} \) generated by Algorithm 3 satisfies

\[
\lim_{t \to \infty} w_t = w^*_\eta \quad \text{almost surely,}
\]

where \( w^*_\eta \) is the unique solution of

\[
(A_{\pi_\mu, \mu_0} + \eta I)w - b_{\mu_\mu} = 0
\] (11)

inside \( B_1 \). Here

\[
A_{\pi_\mu, \mu_\mu} = X^\top D_{\mu_\mu}(I - \gamma P_{\pi_\mu})X, b_{\mu_\mu} = X^\top D_{\mu_\mu}r,
\]

and \( \pi_\mu \) denotes the greedy policy w.r.t. \( x(s, \cdot)^\top w \).

We defer the proof to Section A.5. Analogously to the policy evaluation setting, if we call the solutions of \( A_{\pi_\mu, \mu_\mu} w - b_{\mu_\mu} = 0 \) TD fixed points for control in the discounted setting, then Theorem 4 asserts that Algorithm 3 finds a regularized TD fixed point.

Algorithm 3 and Theorem 4 are significant in two aspects. First, in Algorithm 3, the behavior policy is a function of
Breaking the Deadly Triad with a Target Network

The target network and thus changes every time step. By contrast, previous work on Q-learning with function approximation (e.g., Melo et al. (2008); Mf et al. (2010); Chen et al. (2019b); Cai et al. (2019); Chen et al. (2019a); Lee & He (2019); Xu & Gu (2020); Carvalho et al. (2020); Wang & Zou (2020)) usually assumes the behavior policy is fixed. Though Fan et al. (2020) also adopt a changing behavior policy, they consider bi-level optimization. At each time step, the nested optimization problem must be solved exactly, which is computationally expensive and sometimes unfeasible. To the best of our knowledge, we are the first to analyze Q-learning with function approximation under a changing behavior policy and without nested optimization problems. Compared with the fixed behavior policy setting or the bi-level optimization setting, our two-timescale setting with a changing behavior policy is more closely related to actual practice (e.g., Mnih et al. (2015); Lillicrap et al. (2015)).

Second, Theorem 4 does not enforce any similarity between $\mu_0$ and $\pi_w$; they can be arbitrarily different. By contrast, previous work (e.g., Melo et al. (2008); Chen et al. (2019b); Cai et al. (2019); Xu & Gu (2020); Lee & He (2019)) usually requires the strong assumption that the fixed behavior policy $\mu$ is sufficiently close to the target policy $\pi_w$. As the target policy (i.e., the greedy policy) can change every time step due to the changing action-value estimates, this strong assumption rarely holds. While some work removes this strong assumption, it introduces other problems instead. In Greedy-GQ, Mf et al. (2010) avoid this strong assumption by computing sub-gradients of an MSPBE objective $\text{MSPBE}(w) = \| A_{\pi_w,\mu} w - b_\mu \|^2_{C_{\pi}}$. If linear Q-learning (4) under a fixed behavior policy $\mu$ converges to the minimizer of MSPBE($w$). Greedy-GQ, however, converges only to a stationary point of MSPBE($w$). By contrast, Algorithm 3 converges to a minimizer of our regularized MSPBE (c.f. (11)).

In Coupled Q-learning, Carvalho et al. (2020) avoid this strong assumption by using a target network as well, which they update as

$$\theta_{t+1} \leftarrow \theta_t + \alpha_t \left( (x_t x_t^\top) w_t - \theta_t \right).$$

(12)

This target network update deviates much from the commonly used Polyak-averaging style update, while our (8) is identical to the Polyak-averaging style update most times if the balls for projection are sufficiently large. Coupled Q-learning updates the main network $w$ as usual (see (6)). With the Coupled Q-learning updates (6) and (12), Carvalho et al. (2020) prove that the main network and the target network converge to $\bar{w}$ and $\bar{\theta}$ respectively, which satisfy

$$X \bar{w} = XX^\top D_\mu \mathcal{T}_{\pi_w} X \bar{w}, \quad X \bar{\theta} = \Pi_{D_\mu} \mathcal{T}_{\pi_w} X \bar{w}.$$ 

It is, however, not clear how $\bar{w}$ and $\bar{\theta}$ relate to TD fixed points. Yang et al. (2019) also use a target network to avoid this strong assumption. Their target network update is the same as (8) except that they have only one projection $\Gamma_{B_1}$. Consequently, they face the problem of the reflection term $\zeta(t)$ (c.f. (9)). They also assume the main network $\{w_t\}$ is always bounded, a strong assumption that we do not require. Moreover, they consider a fixed sampling distribution for obtaining i.i.d. samples, while our data collection is done by executing the changing behavior policy $\mu_\theta$ in the MDP.

One limit of Theorem 4 is that the bound on $\|X\|$ (i.e., $C_0$) depends on $1/R_{B_1}$ (see the proof in Section A.5 for the analytical expression), which means $C_0$ could potentially be small. Though we can use a small $\eta$ accordingly to ensure that the regularization effect of $\eta$ is modest, a small $C_0$ may not be desirable in some cases. To address this issue, we propose Gradient Q-learning with a Target Network, inspired by Greedy-GQ. We first equip MSPBE($w$) with a changing behavior policy $\mu_w$, yielding the following objective $\| A_{\pi_w,\mu_w} w - b_\mu \|^2_{C_{\pi}}$. We then use the target network $\theta$ in place of $w$ in the non-convex components, yielding

$$L(w, \theta) \equiv \| A_{\pi_w,\mu_w} w - b_\mu \|^2_{C_{\pi}} + \eta \| w \|^2,$$

(13)

where we have also introduced a ridge term. At time step $t$, we update $w_t$ following the gradient $\nabla w L(w, \theta_t)$ and update the target network $\theta_t$ as usual. Details are provided in Algorithm 4, where the additional weight vector $u \in \mathbb{R}^K$ results from a weight duplication trick (see Sutton et al. (2009b,a) for details) to address a double sampling issue in estimating $\nabla w L(w, \theta)$.

Algorithm 4 Gradient Q-learning with a Target Network

INPUT: $\eta > 0, R_{B_1} > R_{B_2} > 0$
Initialize $\theta_0 \in B_1$ and $S_0$
Sample $A_0 \sim \mu_\theta (\cdot | S_0)$
for $t = 0, 1, \ldots$
do
Execute $A_t$, get $S_{t+1}$ and $S_{t+1}$
Sample $A_{t+1} \sim \mu_\theta (\cdot | S_t)$
$x_{t+1} = \sum_a \pi_\theta (a \mid S_{t+1}) x(S_{t+1}, a')$
$\delta_t = R_{t+1} + \gamma x_{t+1}^\top w_t - x_t^\top w_t$
$u_{t+1} = u_t + \eta (\delta_t - x_t^\top u_t) x_t$
$w_{t+1} = w_t + \alpha (x_t - x_{t+1}) x_t^\top u_t - \eta \| w_t \|
\theta_{t+1} = \Gamma_{B_1}(\theta_t + \beta_t (\Gamma_{B_2}(w_{t+1}) - \theta_t))$
end for

In Algorithm 3, the target policy $\pi_w$ is a greedy policy, which is not continuous in $w$. This discontinuity is not a problem there but requires sub-gradients in the analysis of Algorithm 4, which complicates the presentation. We, therefore, impose Assumption 5.2 on $\pi_w$ as well.

Assumption 5.3. $\pi_\theta (a \mid s)$ is Lipschitz continuous in $\theta$.

Though a greedy policy no longer satisfies Assumption 5.3, we can simply use a softmax policy.
Theorem 5. Under Assumptions 2.2, 3.1, 3.5, & 5.1-5.3, there exist positive constants $C_0$ and $C_1$ such that for all $\|X\| < C_0$, $R_{B_1} > R_{B_2} > C_1$, the iterate $\{w_t\}$ generated by Algorithm 4 satisfies
\[
\lim_{t \to \infty} w_t = w_0^\ast \text{ almost surely,}
\]
where $w_0^\ast$ is the unique solution of
\[
(A_{\pi^\ast, \mu^\ast}^\top C_{\mu^\ast}^{-1} A_{\pi^\ast, \mu^\ast} + \eta I)w = A_{\pi^\ast, \mu^\ast}^\top C_{\mu^\ast}^{-1} \bar{b}_{\mu^\ast}.
\]

We defer the proof to Section A.6. Importantly, the Algorithm 5

\[
Q = \{\text{iterate} C_L\} \Rightarrow \text{producing a target network and ridge regularization in (5)}
\]

point.

w to instead of whether it converges or not. If we assume

\[
\|X\| (\text{or equivalently, } \eta) \text{ in Theorem 5 is only used to fulfill Assumption 3.4, without which } \{\theta_t\} \text{ in Algorithm 4 still converges to an invariant set of the ODE (10).}
\]

This condition is to investigate where the iterate converges to instead of whether it converges or not. If we assume $w_0^\ast = \lim_{t \to \infty} w_t$ exists and $A_{\pi^\ast, \mu^\ast}w_0^\ast = \bar{b}_{\mu^\ast} = 0$, indicating $w_0^\ast$ is a TD fixed point. $w_0^\ast$ can therefore be regarded as a regularized TD fixed point, though how the regularization is imposed here (c.f. (13)) is different from that in Algorithm 3 (c.f. (11)).

Average-reward Setting. Similar to Algorithm 2, introducing a target network and ridge regularization in (5) yields Differential Q-learning with a Target Network (Algorithm 5). Similar to Algorithm 2, $\{B_i\}$ are now balls in $\mathbb{R}^{K+1}$.

Algorithm 5 Diff. Q-learning with a Target Network

\[
\text{INPUT: } \eta > 0, R_{B_1} > R_{B_2} > 0
\]

Initialize $[\theta_0^i, \theta_0^w]^\top \in B_1 \text{ and } S_0$

Sample $A_0 \sim \mu(\cdot|S_0)$

for $t = 0, 1, \ldots$ do

Execute $A_t$, get $R_{t+1}$ and $S_{t+1}$

Sample $A_{t+1} \sim \mu_{\pi^\ast}(\cdot|S_{t+1})$

$\delta_t = R_{t+1} - \theta^i_t + \max_{a\in X} x(S_{t+1}, a)^\top \theta^w - x_t^\top w_t$

$w_{t+1} = w_t + \alpha_t \delta_t x_t - \alpha_t \nu_t$

$\theta^i_t = R_{t+1} + \max_{a\in X} x(S_{t+1}, a)^\top \theta^w - x_t^\top w_t - \bar{r}_t$

$\bar{r}_{t+1} = \bar{r}_t + \alpha_t \delta_t^i$

$[\theta^i_{t+1}, \theta^w_{t+1}] = \Gamma B_t \left( \begin{bmatrix} \theta^i_t \\ \theta^w_t \end{bmatrix} + \beta_t (\Gamma B_t ( \begin{bmatrix} \bar{r}_t \\ w_t \end{bmatrix} ) - \begin{bmatrix} \theta^i_t \\ \theta^w_t \end{bmatrix} ) \right)$

end for

Theorem 6. Under Assumptions 2.2, 3.1, 3.5, 5.1, & 5.2, let $L_\mu$ denote the Lipschitz constant of $\mu_0$, for any $\xi \in (0, 1), R_{B_1} > R_{B_2} > R_{B_3} \geq \xi > 0$, there exist constants $C_0$ and $C_1$ such that for all $\|X\| < C_0, L_\mu < C_1$, the iterate $\{w_t\}$ generated by Algorithm 5 satisfies
\[
\lim_{t \to \infty} w_t = w_0^\ast \text{ almost surely,}
\]

where $w_0^\ast$ is the unique solution of

\[
(A_{\pi^\ast, \mu^\ast}^\top + \eta I)w - \bar{b}_{\mu^\ast} = 0 \text{ inside } B_1,
\]

\[
\bar{A}_{\pi^\ast, \mu^\ast} = \frac{X(D_{\mu^\ast} - d_{\mu^0} d_{\mu^\ast}^\top (I - P_{\pi^\ast})) X}{X^\top (D_{\mu^\ast} - d_{\mu^0} d_{\mu^\ast}^\top) X},
\]

and $\pi^\ast$ is a greedy policy w.r.t. $x(s, \cdot)^\top w$.

We defer the proof to Section A.7. Theorem 6 requires $\mu_0$ to be sufficiently smooth, which is a standard assumption even in the on-policy setting (e.g., Melo et al. (2008); Zou et al. (2019)). It is easy to see that if (5) converges, it converges to a solution of $A_{\pi^\ast, \mu^\ast}w - \bar{b}_{\mu^\ast} = 0$, which we call a TD fixed point for control in the average-reward setting. Theorem 6, which shows that Algorithm 5 finds a regularized TD fixed point, is to the best of our knowledge the first theoretical study for linear Q-learning in the average-reward setting.

6. Experiments

All the implementations are publicly available. \textsuperscript{1}

We first use Kolter’s example (Kolter, 2011) to investigate how $\eta$ influences the performance of $w_0^\ast$ in the policy evaluation setting. Details are provided in Section D.1. This example is a two-state MDP with small representation error (i.e., $\|\Pi d_{\pi^\ast} v_{\tau} - v_{\pi^\ast}\|$ is small). We vary the sampling probability of one state $(d_{\pi^\ast}(s_1))$ and compute corresponding $w_0^\ast$ analytically. Figure 1a shows that with $\eta = 0$, the performance of $w_0^\ast$ becomes arbitrarily poor when $d_{\pi^\ast}(s_1)$ approaches around 0.71. With $\eta = 0.01$, the spike exists as well. If we further increase $\eta$ to 0.02 and 0.03, the performance for $w_0^\ast$ becomes well bounded. This confirms the potential advantage of the regularized TD fixed points.

We then use Baird’s example (Baird, 1995) to empirically investigate the convergence of the algorithms we propose. We use exactly the same setup as Chapter 11.2 of Sutton & Barto (2018). Details are provided in Section D.2. In particular, we consider three settings: policy evaluation (Figure 1b), control with a fixed behavior policy (Figure 1c), and control with an action-value dependent behavior policy (Figure 1d). For the policy evaluation setting, we compare a TD version of Algorithm 1 and standard Off-Policy Linear TD (possibly with ridge regularization). For the two control settings, we compare Algorithm 3 with standard linear Q-learning (possibly with ridge regularization). We use constant learning rates and do not use any projection in all the compared algorithms. The exact update rules are provided in Section D.2. Interestingly, Figures 1b-d show that even with $\eta = 0$, i.e., no ridge regularization, our algorithms with target network still converge in the tested domains. By contrast, without a target network, even when mild regularization is imposed, standard off-policy algorithms still diverge. This confirms the importance of the target network.

\textsuperscript{1}https://github.com/ShangtongZhang/DeepRL
7. Discussion and Related Work

For all the algorithms we propose, both the target network and the ridge regularization are at play. One may wonder if it is possible to ensure convergence with only ridge regularization without the target network. In the policy evaluation setting, the answer is affirmative. Applying ridge regularization in (2) directly yields

\[ w_{t+1} \leftarrow w_t + \alpha_t \delta_t x_t - \alpha_t \eta w_t, \tag{14} \]

where \( \delta_t \) is defined in (2). The expected update of (14) is

\[ \Delta w = b - (A + \eta I)w \]
\[ \quad \pm b - X^T D_{\pi} X w + \gamma X^T D_{\pi} (P_{\pi} X w) - \eta w. \]

If its Jacobian w.r.t. \( w \), denoted as \( J_w(\Delta_w) \), is negative definite, the convergence of \( \{w_t\} \) is expected (see, e.g., Section 5.5 of Vidyasagar (2002)). This negative definiteness can be easily achieved by ensuring \( \eta > \|X\|^2 \|D_{\pi}(I - \gamma P_{\pi})\| \) (see Diddigi et al. (2019) for similar techniques). This direct ridge regularization, however, would not work in the control setting. Consider, for example, linear Q-learning with ridge regularization (i.e., (14) with \( \delta_t \) defined in (4)). The Jacobian of its expected update is \( J_w(b_{\mu,w} - (A_{\pi,w,\mu,w} + \eta I)w) \).

It is, however, not clear how to ensure this Jacobian is negative definite by tuning \( \eta \). By using a target network for bootstrapping, \( P_{\pi} X w \) becomes \( P_{\pi} X \theta \). So \( J_w(\Delta_w) \) becomes \( -J_w(X^T D_{\mu} X w + \eta w) \), which is always negative definite. Similarly, \( J_w(b_{\mu,w} - (A_{\pi,w,\mu,w} + \eta I)w) \) becomes \( -J_w(X^T D_{\mu} X w + \eta w) \) in Algorithm 3, which is always negative definite regardless of \( \theta \). The convergence of the main network \( \{w_t\} \) can, therefore, be expected. The convergence of the target network \( \{\theta_t\} \) is then delegated to Theorem 1. Now it is clear that in the deadly triad setting, the target network stabilizes training by ensuring the Jacobian of the expected update is negative definite. One may also wonder if it is possible to ensure convergence with only the target network without ridge regularization. The answer is unclear. In our analysis, the conditions on \( \|X\| \) (or equivalently, \( \eta \)) are only sufficient and not necessarily necessary. We do see in Figure 1 that even with \( \eta = 0 \), our algorithms still converge in the tested domains. How small \( \eta \) can be in general and under what circumstances \( \eta \) can be 0 are still open problems, which we leave for future work. Further, ridge regularization usually affects the convergence rate of the algorithm, which we also leave for future work.

In this paper, we investigate target network as one possible solution for the deadly triad. Other solutions include Gradient TD methods (Sutton et al. (2009b; 2016) for the discounted setting; Zhang et al. (2021) for the average-reward setting) and Empathic TD methods (Sutton et al. (2016) for the discounted setting). Other convergence results of Q-learning with function approximation include Tsitsiklis & Van Roy (1996); Szepesvári & Smart (2004), which require special approximation architectures, Wen & Van Roy (2013); Du et al. (2020), which consider deterministic MDPs, Li et al. (2011); Du et al. (2019), which require a special oracle to guide exploration, Chen et al. (2019a), which require matrix inversion every time step, and Wang et al. (2019); Yang & Wang (2019; 2020); Jin et al. (2020), which consider linear MDPs (i.e., both \( p \) and \( r \) are assumed to be linear). Achiam et al. (2019) characterize the divergence of Q-learning with nonlinear function approximation via Taylor expansions and use preconditioning to empirically stabilize training. Van Hasselt et al. (2018) empirically study the role of a target network in the deadly triad setting in deep RL, which is complementary to our theoretical analysis.

Regularization is also widely used in RL. Yu (2017) introduce a general regularization term to improve the robustness of Gradient TD algorithms. Du et al. (2017) use ridge regularization in MSPBE to improve its convexity. Zhang et al. (2020) use ridge regularization to stabilize the training of critic in an off-policy actor-critic algorithm. Kolter & Ng
8. Conclusion

In this paper, we proposed and analyzed a novel target network update rule, with which we improved several linear RL algorithms that are known to diverge previously due to the deadly triad. Our analysis provided a theoretical understanding, in the deadly triad setting, of the conventional wisdom that a target network stabilizes training. A possibility for future work is to introduce nonlinear function approximation, possibly over-parameterized neural networks, into our analysis.
