Ordinary least squares (OLS) is the default method for fitting linear models, but is not applicable for problems with dimensionality larger than the sample size. For these problems, we advocate the use of a generalized version of OLS motivated by ridge regression, and propose two novel three-step algorithms involving least squares fitting and hard thresholding. The algorithms are methodologically simple to understand intuitively, computationally easy to implement efficiently, and theoretically appealing for choosing models consistently. Numerical exercises comparing our methods with penalization-based approaches in simulations and data analyses illustrate the great potential of the proposed algorithms.

1. INTRODUCTION

Long known for its consistency, simplicity and optimality under mild conditions, ordinary least squares (OLS) is the most widely used technique for fitting linear models. Developed originally for fitting fixed dimensional linear models, unfortunately, classical OLS fails in high dimensional linear models where the number of predictors $p$ far exceeds the number of observations $n$. To deal with this problem, Tibshirani (1996) proposed $\ell_1$-penalized regression, a.k.a, lasso, which triggered the recent overwhelming exploration in both theory and methodology of penalization-based methods. These methods usually assume that only a small number of coefficients are nonzero (known as the sparsity assumption), and minimize the same least squares loss function as OLS by including an additional penalty on the coefficients, with the typical choice being the $\ell_1$ norm. Such “penalization” constrains the solution space to certain directions favoring sparsity of the solution, and thus overcomes the non-unique issue with OLS. It yields a sparse solution and achieves model selection consistency and estimation consistency under certain conditions. See Zhao and Yu (2006); Fan and Li (2001); Zhang (2010); Zou and Hastie (2005).

Despite the success of the methods based on regularization, there are important issues that can not be easily neglected. On the one hand, methods using convex penalties, such as lasso, usually require strong conditions for model selection consistency (Zhao and Yu, 2006; Lounici, 2008). On the other hand, methods using non-convex penalties (Fan and Li, 2001; Zhang, 2010) that can achieve model selection consistency under mild conditions often require huge computational expense. These concerns have limited the practical use of regularized methods, motivating alternative strategies such as direct hard thresholding (Jain et al., 2014).

In this article, we aim to solve the problem of fitting high-dimensional sparse linear models by reconsidering OLS and answering the following simple question: Can ordinary least squares consistently fit these models with some suitable algorithms? Our result provides an affirmative answer to this question under fairly general settings. In particular, we give a generalized form of OLS in high dimensional linear regression, and develop two algorithms that can consistently estimate the coefficients and recover the support. These algorithms involve least squares type of fitting and hard thresholding, and are non-iterative in nature. Extensive empirical experiments are provided in Section 4 to compare the proposed estimators to many existing penalization methods. The performance of the new estimators is very competitive under various setups in terms of model selection, parameter estimation and computational time.
1.1. Related Works

The work that is most closely related to ours is Yang et al. (2014), in which the authors proposed an algorithm based on OLS and ridge regression. However, both their methodology and theory are still within the $\ell_1$ regularization framework, and their conditions (especially their C-Ridge and C-OLS conditions) are overly strong and can be easily violated in practice. Jain et al. (2014) proposed an iterative hard thresholding algorithm for sparse regression, which shares a similar spirit of hard thresholding as our algorithm. Nevertheless, their motivation is completely different, their algorithm lacks theoretical guarantees for consistent support recovery, and they require an iterative estimation procedure.

1.2. Our Contributions

We provide a generalized form of OLS for fitting high dimensional data motivated by ridge regression, and develop two algorithms that can consistently fit linear models on weakly sparse coefficients. We summarize the advantages of our new algorithms in three points.

Our algorithms work for highly correlated features under random designs. The consistency of the algorithms relies on a moderately growing conditional number, as opposed to the strong irrepresentable condition (Zhao and Yu, 2006; Wainwright, 2009) required by lasso. Our algorithms can achieve consistent identify strong signals for ultra-high dimensional data ($\log p = o(n)$) with only a bounded variance assumption on the noise $\varepsilon$, i.e., $\text{var}(\varepsilon) < \infty$. This is remarkable as most methods (c.f. Zhang (2010); Yang et al. (2014); Cai and Wang (2011); Wainwright (2009); Zhang and Huang (2008); Wang and Leng (2015)) that work for $\log p = o(n)$ case rely on a sub-Gaussian tail/bounded error assumption, which might fail to hold for real data.

Lounici (2008) proved that lasso error assumption, which might fail to hold for real data.

2. HIGH DIMENSIONAL ORDINARY LEAST SQUARES

Consider the usual linear model

$$Y = X\beta + \varepsilon,$$

where $X$ is the $n \times p$ design matrix, $Y$ is the $n \times 1$ response vector and $\beta$ is the coefficient. In the high dimensional literature, $\beta_i$’s are routinely assumed to be zero except for a small subset $S^* = \text{supp}(\beta)$. In this paper, we consider a slightly more general setting, where $\beta$ is not exactly sparse, but consists of both strong and weak signals. In particular, we defined $S^*$ and $S_s$

$$S^* = \{k : |\beta_k| \geq \tau^*\}, \quad S_s = \{k : |\beta_k| \leq \tau_s\}$$

as the strong and weak signal sets and $S^* \cup S_s = \{1, 2, \cdots, p\}$. The algorithms developed in this paper is to recover the strong signal set $S^*$. The specific relationship between $\tau^*$ and $\tau_s$ will be detailed later.

To carefully tailor the low-dimensional OLS estimator in a high dimensional scenario, one needs to answer the following two questions: i) What is the correct form of OLS in the high dimensional setting? ii) How to correctly use this estimator? To answer these, we reconsider OLS from a different perspective by viewing the OLS as the limit of the ridge estimator with the ridge parameter going to zero, i.e.,

$$(X^TX)^{-1}X^TY = \lim_{r \to 0} (X^TX + rI_p)^{-1}X^TY.$$

One nice property of the ridge estimator is that it exists regardless of the relationship between $p$ and $n$. A keen observation reveals the following relationship immediately.

**Lemma 1.** For any $p, n, r > 0$, we have

$$(X^TX + rI_p)^{-1}X^TY = X^T(XX^T + rI_n)^{-1}Y. \quad (1)$$

Notice that the right hand side of (1) exists when $p > n$ and $r = 0$. Consequently, we can naturally extend the classical OLS to the high dimensional scenario by letting $r$ tend to zero in (1). Denote this high dimensional version of the OLS as

$$\hat{\beta}^{(HD)} = \lim_{r \to 0} X^T(XX^T + rI_n)^{-1}Y = X^T(XX^T)^{-1}Y.$$

Unfortunately, $\hat{\beta}^{(HD)}$ does not have good general performance in estimating sparse vectors in high-dimensional cases. Instead of directly estimating $\beta$ as $\hat{\beta}^{(HD)}$, however, this new estimator of $\beta$ may be used for dimension reduction by observing $\hat{\beta}^{(HD)} = X^T(XX^T)^{-1}X\beta +$
Section 4. A clear diagonal dominance pattern is visible in standardized design matrix directly from the real data in concrete procedure is described in Algorithm 1. The input parameter \( d < n \) is chosen as \( \sigma \) the largest \( \delta \) in \( \Phi \) is close to a diagonally dominant matrix and \( \beta \) is sparse, then the strong and weak signals can be separated by simply thresholding the small entries of \( \hat{\beta}^{(HD)} \). The exact meaning of this statement will be discussed in the next section. Some simple examples demonstrating the diagonal dominance of \( X^T (X X^T)^{-1} X \) are illustrated immediately in Figure 1, where the rows of \( X \) in the left two plots are drawn from \( N(0, \Sigma) \) with \( \sigma_{ij} = 0.6 \) or \( \sigma_{ij} = 0.99 \). The sample size and data dimension are chosen as \((n, p) = (50, 1000)\). The right plot takes the standardized design matrix directly from the real data in Section 4. A clear diagonal dominance pattern is visible in each plot.

This ability to separate strong and weak signals allows us to first obtain a smaller model with size \( d \) such that \( |S^*| < d < n \) containing \( S^* \). Since \( d \) is below \( n \), one can directly apply the usual OLS to obtain an estimator, which will be thresholded further to obtain a more refined model. The final estimator will then be obtained by an OLS fit on the refined model. This three-stage non-iterative algorithm is termed Least-squares adaptive thresholding (LAT) and the concrete procedure is described in Algorithm 1.

**Algorithm 1 The Least-squares Adaptive Thresholding (LAT) Algorithm**

**Initialization:**

1. Input \((Y, X), d, \delta\)

**Stage 1 : Pre-selection**

2. Standardize \( Y \) and \( X \) to \( \tilde{Y} \) and \( \tilde{X} \) having mean 0 and variance 1.
3. Compute \( \hat{\beta}^{(HD)} = \tilde{X}^T (\tilde{X} \tilde{X}^T + 0.1 \cdot I_n)^{-1} \tilde{Y} \). Rank the importance of the variables by \( |\hat{\beta}^{(HD)}_i|\);
4. Denote the model corresponding to the \( d \) largest \( |\hat{\beta}^{(HD)}_i| \) as \( \hat{M}_d \). Alternatively use extended BIC (Chen and Chen, 2008) in conjunction with the obtained variable importance to select the best submodel.

**Stage 2 : Hard thresholding**

5. \( \hat{\beta}^{(OLS)} = (X_{M_d}^T X_{M_d})^{-1} X_{M_d}^T Y; \)
6. \( \hat{\sigma}^2 = \sum_{i=1}^{n} (y - \hat{y})^2/(n - d); \)
7. \( \hat{C} = (X_{M_d}^T X_{M_d})^{-1}; \)
8. Threshold \( \hat{\beta}^{(OLS)} \) by \( \text{MEAN}(\sqrt{2\hat{\sigma}^2 C_{ii} \log(4d/\delta)}) \) or use BIC to select the best submodel. Denote the chosen model as \( \hat{M} \).

**Stage 3 : Refinement**

9. \( \hat{\beta}_{\hat{M}} = (X_{M_d}^T X_{\hat{M}})^{-1} X_{M_d}^T Y; \)
10. \( \hat{\beta}_i = 0, \forall i \notin \hat{M}; \)
11. return \( \hat{\beta} \).

The input parameter \( d \) is the submodel size selected in Stage 1 and \( \delta \) is the tuning parameter determining the threshold in Stage 2. In Stage 1, we use \( \hat{\beta}^{(HD)} = \tilde{X}^T (\tilde{X} \tilde{X}^T + 0.1 \cdot I_n)^{-1} \tilde{Y} \) instead of \( \hat{\beta}^{(HD)} = \tilde{X}^T (\tilde{X} \tilde{X}^T)^{-1} \tilde{Y} \) because \( \tilde{X} \tilde{X}^T \) is rank deficient (the rank is \( n - 1 \)) after standardization. The number 0.1 can be replaced by any arbitrary small number. As noted in Wang and Leng (2015), this additional ridge term is also essential when \( p \) and \( n \) get closer. Our results in Section 3 mainly focus on \( \hat{\beta}^{(HD)} = X^T (X X^T)^{-1} Y \) where \( X \) is assumed to be drawn from a distribution with mean zero, so no standardization or ridge adjustment is required. However, the result is easy to generalize to the case where a ridge term is included. See Wang and Leng (2015).

The Stage 1 of Algorithm 1 is very similar to variable screening methods (Fan and Lv, 2008; Wang and Leng, 2015). However, most screening methods require a sub-Gaussian condition the noise to handle the ultra-high dimensional data where \( \log(p) = o(n) \). In contrast to the existing theory, we prove in the next section a better result that Stage 1 of Algorithm 1 can produce satisfactory submodel even for heavy-tailed noise.

The estimator \( \hat{\beta}^{(OLS)} \) in Stage 2 can be substituted by its ridge counterpart \( \hat{\beta}^{(Ridge)} = (X_{M_d}^T X_{M_d} + rI_d)^{-1} X_{M_d}^T Y \) and \( C \) by \( (X_{M_d}^T X_{M_d} + rI_d)^{-1} \) to stabilize numerical computation. Similar modification can be applied to the Stage 3 as well. The resulted variant of the algorithm is referred to as the Ridge Adaptive Thresholding (RAT) algorithm and described in Algorithm 2.

**Algorithm 2 The Ridge Adaptive Thresholding (RAT) Algorithm**

**Initialization:**

1. Input \((Y, X), d, \delta, r\)

**Stage 1 : Pre-selection**

2. Standardize \( Y \) and \( X \) to \( \tilde{Y} \) and \( \tilde{X} \) having mean 0 and variance 1.
3. Compute \( \hat{\beta}^{(HD)} = \tilde{X}^T (\tilde{X} \tilde{X}^T + 0.1 \cdot I_n)^{-1} \tilde{Y} \). Rank the importance of the variables by \( |\hat{\beta}^{(HD)}_i|\);
4. Denote the model corresponding to the \( d \) largest \( |\hat{\beta}^{(HD)}_i| \) as \( \hat{M}_d \). Alternatively use eBIC in Chen and Chen (2008) in conjunction with the obtained variable importance to select the best submodel.

**Stage 2 : Hard thresholding**

5. \( \hat{\beta}^{(Ridge)} = (X_{M_d}^T X_{M_d} + rI_d)^{-1} X_{M_d}^T Y; \)
6. \( \hat{\sigma}^2 = \sum_{i=1}^{n} (y - \hat{y})^2/(n - d); \)
7. \( \hat{C} = (X_{M_d}^T X_{M_d} + rI_d)^{-1}; \)
8. Threshold \( \hat{\beta}^{(OLS)} \) by \( \text{MEAN}(\sqrt{2\hat{\sigma}^2 C_{ii} \log(4d/\delta)}) \) or use BIC to select the best submodel. Denote the chosen model as \( \hat{M} \).

**Stage 3 : Refinement**

9. \( \hat{\beta}_{\hat{M}} = (X_{M_d}^T X_{\hat{M}} + rI_d)^{-1} X_{M_d}^T Y; \)
10. \( \hat{\beta}_i = 0, \forall i \notin \hat{M}; \)
11. return \( \hat{\beta} \).
We suggest to use 10-fold cross-validation to tune the ridge parameter \( r \). Notice that the model is already small after stage 1, so using cross-validation will not significantly increase the computational burden. The computational performance is illustrated in Section 4.

3. THEORY

In this section, we prove the consistency of Algorithm 1 in recovering \( \Sigma \) and provide concrete forms for all the values needed for the algorithm to work. Recall the linear model \( Y = X\beta + \varepsilon \). We consider the random design where the rows of \( X \) are drawn from an elliptical distribution with covariance \( \Sigma \). It is easy to show that \( x_i \) admits an equivalent representation as

\[
x_i \overset{(d)}{=} L_i \sqrt{p} z_i \Sigma^1/2 = \sqrt{p} L_i z_i \Sigma^1/2.
\]

where \( z_i \) is a p-variate standard Gaussian random variable and \( L_i \) is a nonnegative random variable that is independent of \( z_i \). We denote this distribution by \( EN(L, \Sigma) \). This random design allows for various correlation structures and contains many distribution families that are widely used (Bickel et al., 2009; Raskutti et al., 2010). The noise \( \varepsilon \), as mentioned earlier, is only assumed to have the second-order moment, i.e., \( \operatorname{var}(\varepsilon) = \sigma^2 < \infty \), in contrast to the sub-Gaussian/bounded error assumption seen in most high dimension literature. See Zhang (2010); Yang et al. (2014); Cai and Wang (2011); Wainwright (2009); Zhang and Huang (2008). This relaxation is similar to Lounici (2008); however we do not require any further assumptions needed by Lounici (2008). In Algorithm 1, we also propose to use extended BIC and BIC for parameter tuning. However, the corresponding details will not be pursued here, as their consistency is straightforwardly implied by the results from this section and the existing literature (Chen and Chen, 2008).

As shown in (2), the variable \( L \) controls the signal strength of \( x_i \), we thus need a lower bound on \( L_i \) to guarantee a good signal strength. Define \( \kappa = \operatorname{cond}(\Sigma) \). We state our result in three theorems.

**Theorem 1.** Assume \( x_i \sim EN(L_i, \Sigma) \) with \( E[L_i^{-2}] \leq M_1 \) and \( \varepsilon_i \) is a random variable with a bounded variance \( \sigma^2 \). We also assume \( p > c_0 n \) for some \( c_0 > 1 \) and \( \operatorname{var}(\varepsilon) \leq M_0 \). If \( |S^*| \log p = o(n) \), \( n > 4c_0/(c_0-1)^2 \), and \( \tau^*/\tau_* \geq 4\kappa^2 \), then we can choose \( \gamma \) to be \( 2\kappa^{-2} \log n / \tau_*^2 n^{1/2} \), where \( c_1 \) is some absolute constant specified in Lemma 2 and for any \( \alpha \in (0, 1) \) we have

\[
P(\max_{i \in S^*} |\beta_i^{(HD)}| \leq \gamma \leq \min_{i \in S^*} |\beta_i^{(HD)}|) = 1 - O\left(\frac{\sigma^2 \kappa^4 \log p}{\tau_*^2 n^{1/2}}\right).
\]

Theorem 1 guarantees the model selection consistency of the first stage of Algorithm 1. It only requires a second-moment condition on the noise tail, relaxing the sub-Gaussian assumption seen in other literature. The probability term shows that the algorithm requires the strong signals to be lower bounded by a signal strength of \( \sigma \sqrt{\log p \over n} \).

In addition, a gap of \( \tau^*/\tau_* \geq 4\kappa^2 \) is needed between the strong and the weak signals in order for a successful support recovery.

As \( \gamma \) is not easily computable based on data, we propose to rank the \( |\beta_i^{(HD)}| \)’s and select \( d \) largest coefficients. Alternatively, we can construct a series of nested models formed by ranking the largest \( n \) coefficients and adopt the extended BIC (Chen and Chen, 2008). Once the submodel \( \hat{M}_d \) is obtained, we proceed to the second stage by obtaining an estimate via ordinary least squares \( \hat{\beta}^{(OLS)} \) corresponding to \( \hat{M}_d \). The theory for \( \hat{\beta}^{(OLS)} \) requires more stringent conditions, as we now need to estimate \( \beta_{\hat{M}_d} \) instead of just obtaining a correct ranking. In particular, we have to impose conditions on the magnitude of \( \beta_S \) and the moments of \( L \), i.e., for \( \hat{\beta}^{(OLS)} \) we have the following result.

**Theorem 2.** Assume the same conditions for \( X \) and \( \varepsilon \) as in Theorem 1. We also assume \( n \geq 64c_0 \log p \) and \( d - |S^*| \leq \hat{c} \) for some \( \hat{c} > 0 \). If \( E[L^{-12}] \leq M_1, E[L^{12}] \leq M_2 \), \( \tau_* \leq \frac{\sigma}{\kappa} \sqrt{\log p \over n} \) and there exists some \( \nu \in (0, 1) \) such that
The moment condition on $\tau$ is not tight. We use this number just for simplicity. As shown in Theorem 2, the $l_1$ norm of $\tilde{\beta}_S$ is allowed to grow in a rate of $(\log p)^{2/3} n^{1-4\alpha/3-2\beta/3}$, i.e., our algorithms work for weakly sparse coefficients. However, different from Theorem 1, Theorem 2 imposes an upper bound on $\alpha$. This is mainly due to the different structures between $\hat{\beta}(HD)$ and $\hat{\beta}(OLS)$, i.e., $\hat{\beta}(OLS)$ relies on $L$ for diminishing the weak signals while $\hat{\beta}(HD)$ does not. For ridge regression, we have the following result.

**Theorem 3** (Ridge regression). Assume all the conditions in Theorem 2. If we choose the ridge parameter satisfying

$$r \leq \frac{\sigma(\gamma-\delta)}{162nM_0},$$

then we have

$$P\left(\max_{|\tilde{\beta}_S| \leq \delta} \|\tilde{\beta}(ridge) - \beta\|_\infty \leq 3\sqrt{\frac{\log p}{n^{\alpha}}}\right) = 1 - O\left(\lambda_\gamma \frac{2\log d + 2 M_1 + M_2}{n^{\alpha/4}}\right),$$

i.e., if $\tau^* \geq 3\sqrt{\frac{\log p}{n^{\alpha}}}$, then we can choose $\gamma = 3\sqrt{\frac{\log p}{n^{\alpha}}}$ and

$$\max_{i \in S^*} |\tilde{\beta}_i^{(ridge)}(r)| \leq \gamma' \leq \min_{i \in S^*} |\tilde{\beta}_i^{(ridge)}(r)|$$

with probability tending to 1.

When both the noise $\varepsilon$ and $X$ follows Gaussian distribution and $\tau^* = 0$, we can obtain an more explicit form of the threshold $\gamma'$, as the following Corollary shows.

**Corollary 1** (Gaussian noise). Assume $\varepsilon \sim N(0, \sigma^2)$, $X \sim N(0, \Sigma)$ and $\tau^* = 0$. For any $\delta \in (0, 1)$, define

$$\gamma' = 8\sqrt{2\delta} \sqrt{\frac{2\log(4d/\delta)}{n}},$$

where $\hat{\sigma}$ is the estimated standard error as $\hat{\sigma}^2 = \sum_{i=1}^n \hat{y}_i^2 / (n - d)$. For sufficiently large $n$, if $\delta \leq n - 4K^2 \log(2e/\delta)/c$ for some absolute constants $c, K$ and $\tau^* \geq 24\sqrt{\frac{2e \log(4d/\delta)}{n}}$, then with probability at least $1 - 2\delta$, we have

$$|\beta^{(OLS)}_i| \geq \gamma' \quad \forall i \in S^* \quad \text{and} \quad |\beta^{(OLS)}_i| \leq \gamma' \quad \forall i \notin S^*. $$

Write $C = (X_{M_0}^T X_{M_0})^{-1}$ as in Algorithm 1. In practice, we propose to use $\gamma' = \text{mean}(\sqrt{2\hat{\sigma}^2 C_{ii} \log(4d/\delta)})$ as the threshold (see Algorithm 1), because the estimation error takes a form of $\sqrt{2\hat{\sigma}^2 C_{ii} \log(4d/\delta)}$. Once the final model is obtained, as in Stage 3 of Algorithm 1, we refit it again using ordinary least squares. The final output will have the same output as if we knew $S^* \text{ a priori}$ with probability tending to 1. As implied by Theorem 1 - 3, LAT and RAT can consistently identify strong signals in the ultra-high dimensional $(\log p = o(n))$ setting with only the bounded moment assumption $\text{var}(\varepsilon) < \infty$, in contrast to most existing methods that require $\varepsilon \sim N(0, \sigma^2)$ or $\|\varepsilon\|_\infty < \infty$.

### 4. EXPERIMENTS

In this section, we provide extensive numerical experiments for assessing the performance of LAT and RAT. In particular, we compare the two methods to existing penalized methods including lasso, elastic net (enet (Zou and Hastie, 2005)), adaptive lasso (Zou, 2006), scad (Fan and Li, 2001) and mc+ (Zhang, 2010). As it is well-known that the lasso estimator is biased, we also consider two variations of it by combining lasso with Stage 2 and 3 of our LAT and RAT algorithms, denoted as lasLAT (las1 in Figures) and lasRAT (las2 in Figures) respectively. We note that the lasLat algorithm is very similar to the thresholded lasso (Zou, 2010) with an additional thresholding step. We code LAT and RAT and adaptive lasso in Matlab, use glmnet (Friedman et al., 2010) for enet and lasso, and SparseReg (Zou et al., 2012; Zhou and Lange, 2013) for scad and mc+. Since adaptive lasso achieves a similar performance as lasLat on synthetic datasets, we only report its performance for the real data.

#### 4.1. Synthetic Datasets

The model used in this section for comparison is the linear model $Y = X \beta + \varepsilon$, where $\varepsilon \sim N(0, \sigma^2)$ and $X \sim N(0, \Sigma)$. To control the signal-to-noise ratio, we define $r = \|\beta\|_2/\sigma$, which is chosen to be 2.3 for all experiments. The sample size and the data dimension are chosen to be $(n, p) = (200, 1000)$ or $(n, p) = (500, 10000)$ for all experiments. For evaluation purposes, we consider four different structures of $S$ below.

(i) **Independent predictors.** The support is set as $S = \{1, 2, 3, 4, 5\}$. We generate $X_i$ from a standard multivariate normal distribution with independent components. The coefficients are specified as

$$\beta_i = \begin{cases} (-1)^{u_i}(|N(0, 1)| + 1), & u_i \sim Ber(0.5) \quad i \in S \\ 0 & i \notin S. \end{cases}$$

(ii) **Compound symmetry.** All predictors are equally correlated with correlation $\rho = 0.6$. The coefficients are set to
be $\beta_i = 3$ for $i = 1, \ldots, 5$ and $\beta_i = 0$ otherwise.

(iii) **Group structure.** This example is Example 4 in Zou and Hastie (2005), for which we allocate the 15 true variables into three groups. Specifically, the predictors are generated as

$$
x_{1+3m} = z_1 + N(0, 0.01),
$$

$$
x_{2+3m} = z_2 + N(0, 0.01),
$$

$$
x_{3+3m} = z_3 + N(0, 0.01),
$$

where $m = 0, 1, 2, 3$ and $z_i \sim N(0, 1)$ are independent. The coefficients are set as

$$
\beta_i = 3, \ i = 1, 2, \ldots, 15; \ \beta_i = 0, \ i = 16, \ldots, p.
$$

(iv) **Factor models.** This model is also considered in Meinshausen and Bühlmann (2010) and Cho and Fryzlewicz (2012). Let $\phi_j, j = 1, 2, \ldots, k$ be independent standard normal variables. We set predictors as $x_i = \sum_{j=1}^{k} \phi_j f_{ij} + \eta_i$, where $f_{ij}$ and $\eta_i$ are generated from independent standard normal distributions. The number of factors is chosen as $k = 5$ in the simulation while the coefficients are specified the same as in Example (ii).

To compare the performance of all methods, we simulate 200 synthetic datasets for $(n, p) = (200, 1000)$ and 100 for $(n, p) = (500, 10000)$ for each example, and record i) the root mean squared error (RMSE): $\|\hat{\beta} - \beta\|_2$, ii) the false negatives (# FN), iii) the false positives (# FP) and iv) the actual runtime (in milliseconds). We use the extended BIC (Chen and Chen, 2008) to choose the parameters for any regularized algorithm. Due to the huge computation expense for $\text{scad}$ and $\text{mc+}$, we only find the first $\lceil \sqrt{p} \rceil$ predictors on the solution path (because we know $s \ll \sqrt{p}$). For $\text{RAT}$ and $\text{LAT}$, $d$ is set to $0.3 \times n$. For $\text{RAT}$ and $\text{larsRidge}$, we adopt a 10-fold cross-validation procedure to tune the ridge parameter $r$ for a better finite-sample performance, although the theory allows $r$ to be fixed as a constant. For all hard-thresholding steps, we fix $\delta = 0.5$. The results for $(n, p) = (200, 1000)$ are plotted in Figure 2, 3, 4 and 5 and a more comprehensive result (average values for RMSE, # FPs, # FN) for $(n, p) = (500, 10000)$ is summarized in Table 1.

As can be seen from both the plots and the tables, $\text{LAT}$ and $\text{RAT}$ achieve the smallest RMSE for Example (ii), (iii) and (iv) and are on par with $\text{lasLAT}$ for Example (i). For Example (iii), $\text{RAT}$ and $\text{enet}$ achieve the best performance while all the other methods fail to work. In addition, the runtime of $\text{LAT}$ and $\text{RAT}$ are also competitive compared to that of $\text{lasso}$ and $\text{enet}$. We thus conclude that $\text{LAT}$ and $\text{RAT}$ achieve similar or even better performance compared to the usual regularized methods.

### 4.2. A Student Performance Dataset

We look at one dataset used for evaluating student achievement in Portuguese schools (Cortez and Silva, 2008). The data attributes include student grades and school related features that were collected by using school reports and questionnaires. The particular dataset used here provides the students’ performance in mathematics. The goal of the research is to predict the final grade based on all the attributes.

The original data set contains 395 students and 32 raw attributes. The raw attributes are recoded as 40 attributes and form 780 features after interaction terms are added. We then remove features that are constant for all students. This gives 767 features for us to work with. To compare the performance of all methods, we first randomly split the dataset into 10 parts. We use one of the 10 parts as a test set, fit all the methods on the other 9 parts, and then record their prediction error (root mean square error, RMSE), model size and runtime on the test set. We repeat this procedure until each of the 10 parts has been used for testing. The averaged prediction error, model size and runtime are summarized in Table 2. We also report the performance of the null model which predicts the final grade on the test set using the mean final grade in the training set.

It can be seen that $\text{RAT}$ achieves the smallest cross-validation error, followed by $\text{scad}$ and $\text{mc+}$. In the post-feature-selection analysis, we found that two features, the 1st and 2nd period grades of a student, were selected by all the methods. This result coincides with the common perception that these two grades usually have high impact on the final grade.

In addition, we may also be interested in what happens when no strong signals are presented. One way to do this is to remove all the features that are related to the 1st and 2nd grades before applying the aforementioned procedures. The new result without the strong signals removed are summarized in Table 3.

Table 3 shows a few interesting findings. First, under this artificial weak signal scenario, adaptive lasso achieves the smallest cross-validation error and $\text{RAT}$ is the first runner-up. Second, in Stage 1, lasso seems to provide slightly more robust screening than OLS in that the selected features are less correlated. This might be the reason that $\text{LAT}$ is outperformed by $\text{lasLAT}$. However, in both the strong and weak signal cases, $\text{RAT}$ is consistently competitive in terms of performance.

### 5. CONCLUSION

We have proposed two novel algorithms $\text{Lat}$ and $\text{Rat}$ that only rely on least-squares type of fitting and hard threshold-

The two methods are simple, easily implementable, and can consistently fit a high dimensional linear model and recover its support. The performance of the two methods are competitive compared to existing regularization methods. It is of great interest to further extend this framework to other models such as generalized linear models and models for survival analysis.
