Efficient Distributed Learning with Sparsity

Jialei Wang1 Mladen Kolar 1 Nathan Srebro 2 Tong Zhang3

Abstract

We propose a novel, efficient approach for distributed sparse learning with observations randomly partitioned across machines. In each round of the proposed method, worker machines compute the gradient of the loss on local data and the master machine solves a shifted $\ell_1$ regularized loss minimization problem. After a number of communication rounds that scales only logarithmically with the number of machines, and independent of other parameters of the problem, the proposed approach provably matches the estimation error bound of centralized methods.

1. Introduction

We consider learning a sparse linear regressor $\beta$ minimizing the population objective:

$$\beta^* = \arg \min_\beta \mathbb{E}_{X,Y \sim D} [\ell(Y, \langle X, \beta \rangle)],$$

where $(X, Y) \in \mathcal{X} \times \mathcal{Y} \subseteq \mathbb{R}^p \times \mathcal{Y}$ are drawn from an unknown distribution $D$ and $\ell(\cdot, \cdot)$ is a convex loss function, based on $N$ i.i.d. samples $\{x_i, y_i\}_{i=1}^N$ drawn from $D$, and when the support $S := \text{support}(\beta^*) = \{j \in [p] \mid \beta^*_j \neq 0\}$ of $\beta^*$ is small, $|S| \leq s$. In a standard single-machine setting, a common empirical approach is to minimize the $\ell_1$ regularized empirical loss (see, e.g., (2) below). Here we consider a setting where data are distributed across $m$ machines, and, for simplicity, assume $\sum_{i=1}^m n_i = N = nm$, so that each machine $j$ has access to $n_i$ i.i.d. observations (from the same source $D$) $\{x_{ji}, y_{ji}\}_{i=1}^{n_i}$ (equivalently, that $N = nm$ samples are randomly partitioned across machines).

The main contribution of the paper is a novel algorithm for estimating $\beta^*$ in a distributed setting. Our estimator is able to achieve the performance of a centralized procedure that has access to all data, while keeping computation and communication costs low. Compared to the existing one-shot estimation approach (Lee et al., 2015b), our method can achieve the same statistical performance without performing the expensive debiasing step. As the number of communication rounds increases, the estimation accuracy improves until matching the performance of a centralized procedure, which happens after the logarithm of the total number of machines rounds. Furthermore, our results can be achieved under weak assumptions on the data generating procedure.

We assume that the communication occurs in rounds. In each round, machines exchange messages with the master machine. Between two rounds, each machine only computes based on its local information, which includes local data and previous messages (Zhang et al., 2013; Shamir & Srebro, 2014; Arjevani & Shamir, 2015). In a non-distributed setting, efficient estimation procedures need to balance statistical efficiency with computation efficiency (runtime). In a distributed setting, the situation is more complicated and we need to balance two resources, local runtime and number of rounds of communication, with the statistical error. The local runtime refers to the amount of work each machine needs to do. The number of rounds of communication refers to how often do local machines need to exchange messages with the master machine. We compare our procedure to other algorithm using the aforementioned metrics.

We consider the following two baseline estimators of $\beta^*$: the local estimator uses data available only on the master (first) machine and ignores data available on other machines. In particular, it computes

$$\hat{\beta}_{\text{local}} = \arg \min_\beta \frac{1}{n} \sum_{i=1}^n \ell(y_{1i}, \langle x_{1i}, \beta \rangle) + \lambda \|\beta\|_1$$

using locally available data. The local procedure is efficient in both communication and computation, however, the resulting estimation error is large compared to an estimator that uses all of the available data. The other idealized baseline is the centralized estimator

$$\hat{\beta}_{\text{centralize}} = \arg \min_\beta \frac{1}{mn} \sum_{j=1}^m \sum_{i=1}^n \ell(y_{ji}, \langle x_{ji}, \beta \rangle) + \lambda \|\beta\|_1.$$
Efficient Distributed Learning with Sparsity

Our method (EDSL) addresses the aforementioned issues of Avg-Debias. Table 1 summarizes the resources required for the approaches discussed above to solve the distributed sparse linear regression problems.

**Parallel Work** In parallel work (publicly announced on arXiv simultaneously with the results in this contribution), Jordan et al. (2016) present a method which is equivalent to the first iteration of our method, and thus achieves the same computational advantage over Avg-Debias as depicted in the left column of Table 1 and discussed in the first and third bullet points above. Jordan et al. extend the idea in ways different and orthogonal to this submission, by considering also low-dimensional and Bayesian inference problems. Still, for high-dimensional problems, they only consider a one-shot procedure, and so do not achieve statistical optimality in the way our method does, and do not allow using $n \leq ms^2 \log p$ samples per machine (see right half of Table 1). The improved one-shot approach is thus a parallel contribution, made concurrently by Jordan et al. and by us, while the multi-step approach and accompanied reduction in required number of samples (discussed in the second bullet point above) and improvement in statistical accuracy is a distinct contribution of this this submission.

**Other Related Work** A large body of literature exists on distributed optimization for modern massive data sets (Dekel et al., 2012; Duchi et al., 2012; 2014; Zhang et al., 2013b; Zinkevich et al., 2010; Boyd et al., 2011; Balcan et al., 2012; Yang, 2013; Jaggi et al., 2014; Ma et al., 2015; Shamir & Srebro, 2014; Zhang & Xiao, 2015; Lee et al., 2015a; Arjevani & Shamir, 2015). A popular approach to distributed estimation is averaging estimators formed locally by different machines (Mcdonald et al., 2009; Zinkevich et al., 2010; Zhang et al., 2012; Huang & Huo, 2015). Divide-and-conquer procedures also found applications in statistical inference (Zhao et al., 2014a; Cheng & Shang, 2015; Lu et al., 2016). Shamir & Srebro (2014) and Rosenblatt & Nadler (2014) showed that averaging local estimators at the end will have bad dependence on either condition number or dimension of the problem. Yang (2013), Jaggi et al. (2014) and Smith et al. (2016) studied distributed optimization using stochastic (dual) coordinate descent, these approaches try to find a good balance between computation and communication, however, their communication com-

Table 1. Comparison of resources required for matching the centralized error bound of various approaches for high-dimensional distributed sparse linear regression problems, where $T_{lasso}(n,p)$ is the runtime for solving a generalized lasso problem of size $n \times p$.

Unfortunately, due to data being huge and communication expensive, we cannot compute the centralized estimator, even though it achieves the optimal statistical error.

In a related setting, Lee et al. (2015b) studied a one-shot approach to learning $\beta^*\$, called Avg-Debias, that is based on averaging the debiased lasso estimators (Zhang & Zhang, 2013). Under strong assumptions on the data generating procedure, their approach matches the centralized error bound after one round of communication. While an encouraging result, there are limitations to this approach, that we list below.

- The debiasing step in Avg-Debias is computationally heavy as it requires each local machine to estimate a $p \times p$ matrix. For example, Javanmard (2014) (section 5.1) transforms the problem of estimating the debiasing matrix $\Theta$ into $p$ generalized lasso problems. This is computationally prohibitive for high-dimensional problems (Zhang & Zhang, 2013; Javanmard & Montanari, 2014). In comparison, our procedure requires only solving one $\ell_1$ penalized objective in each iteration, which has the same time complexity as computing $\hat{\beta}_{local}$ in (2). See Section 2 for details.

- Avg-Debias procedure only matches the statistical error rate of the centralized procedure when the sample size per machine satisfies $n \geq ms^2 \log p$. Our approach improves this sample complexity to $n \geq s^2 \log p$.

- Avg-Debias procedure requires strong conditions on the data generating process. For example, the data matrix is required to satisfy the generalized coherence condition for debiasing to work$^2$. As we show here, such a condition is not needed for consistent high-dimensional estimation in a distributed setting. Instead, we only require standard restricted eigenvalue condition that are commonly assumed in the high-dimensional estimation literature.

\footnote{The generalized coherence states that there exists a matrix $\Theta$, such that $\|\Sigma_\Theta - I_p\|_2 \leq \sqrt{\frac{\log p}{n}}$, where $\Sigma$ is the empirical covariance matrix.}

Our method (EDSL) addresses the aforementioned issues of Avg-Debias.
Efficient Distributed Learning with Sparsity

Complexity depends badly on the condition number. As a result, they are not better than first-order approaches, such as (proximal) accelerated gradient descent (Nesterov, 1983), in terms of communication. Shamir et al. (2014) and Zhang & Xiao (2015) proposed truly communication-efficient distributed optimization algorithms. They leveraged the local second-order information and, as a result, obtained milder dependence on the condition number compared to the first-order approaches (Boyd et al., 2011; Shamir & Srebro, 2014; Ma et al., 2015). Lower bounds were studied in Zhang et al. (2013a), Braverman et al. (2015), and Arjevani & Shamir (2015). However, it is not clear how to extend these existing approaches to problems with non-smooth objectives, including the $\ell_2$ regularized problems.

Most of the above mentioned work is focused on estimators that are (asymptotically) linear. Averaging at the end reduces the variance of the these linear estimators, resulting in an estimator that matches the performance of a centralized procedure. Zhang et al. (2013c) studied averaging local estimators obtained by the penalized kernel ridge regression, with the $\ell_2$ penalty was chosen smaller than usual to avoid the large bias problem. The situation in a high-dimensional setting is not so straightforward, since the sparsity inducing penalty introduces the bias in a non-linear way. Zhao et al. (2014b) illustrated how averaging debiased high-dimensional estimators can be used for efficient inference in a high-dimensional setting. Averaging debiased high-dimensional estimators was subsequently used in Lee et al. (2015b) for distributed estimation, multi-task learning (Wang et al., 2015), and statistical inference (Battey et al., 2015).

Notation. We use $[n]$ to denote the set $\{1, \ldots, n\}$. For a vector $a \in \mathbb{R}^n$, we let $\text{support}(a) = \{j : a_j \neq 0\}$ be the support, $\|a\|_q := \left(\sum_{i=1}^n |a_i|^q\right)^{1/q}$ for $q \in [1, \infty)$, the $\ell_q$-norm defined as $\|a\|_{\ell_q} = (\sum_{i \in [n]} |a_i|^q)^{1/q}$, and $\|a\|_{\ell_\infty} = \max_{i \in [n]} |a_i|$. For a matrix $A \in \mathbb{R}^{n_1 \times n_2}$, we use the following element-wise $\ell_2$ matrix norms $\|A\|_{\ell_2} = \max_{i \in [n_1], j \in [n_2]} |a_{ij}|$. Denote $I_n$ as $n \times n$ identity matrix. For two sequences of numbers $\{a_n\}_{n=1}^\infty$ and $\{b_n\}_{n=1}^\infty$, we use $a_n = O(b_n)$ to denote that $a_n \leq Cb_n$ for some finite positive constant $C$, and for all $n$ large enough. If $a_n = O(b_n)$ and $b_n = O(a_n)$, we use the notation $a_n = O(b_n)$ and $a_n \asymp b_n$ for $b_n = O(a_n)$.

Paper Organization. We describe our method in Section 2, and present the main results in the context of sparse linear regression in Section 3, and provide a generalized theory in Section 4. We demonstrate the effectiveness of the proposal via experiments in Section 5, and conclude the paper with discussions in Section 6. In Appendix, in Section A we illustrate some concrete examples of the general results in Section 4, and all proofs are deferred in Section B. More experimental results are presented in Section C.

2. Methodology

In this section, we detail our procedure for estimating $\beta^*$ in a distributed setting. Algorithm 1 provides an outline of the steps executed by the master and worker nodes. Let

$$L_j(\beta) = \frac{1}{n} \sum_{i=1}^n \ell(y_{ji}, \langle x_{ji}, \beta \rangle), \quad j \in [m],$$

be the empirical loss at each machine. Our method starts by solving a local $\ell_1$ regularized $M$-estimation program. At iteration $t = 0$, the master (first) machine obtains $\hat{\beta}_0$ as a minimizer of the following program

$$\min_{\beta} L_1(\beta) + \lambda \|\beta\|_1, \quad \text{(3)}$$

The vector $\hat{\beta}_0$ is broadcasted to all other machines, which use it to compute a gradient of the local loss at $\hat{\beta}_0$. In particular, each worker computes $\nabla L_j(\hat{\beta}_0)$ and communicates it back to the master. This constitutes one round of communication. At the iteration $t + 1$, the master solves the shifted $\ell_1$ regularized problem

$$\hat{\beta}_{t+1} = \arg\min_{\beta} L_1(\beta) + \left\langle \frac{1}{m} \sum_{j=1}^m \nabla L_j(\hat{\beta}_t) - \nabla L_1(\hat{\beta}_t), \beta \right\rangle + \lambda_{t+1} \|\beta\|_1. \quad \text{(4)}$$

A minimizer $\hat{\beta}_{t+1}$ is communicated to other machines, which use it to compute the local gradient $\nabla L_j(\hat{\beta}_{t+1})$ as before.

Formulation (4) is inspired by the proposal in Shamir et al. (2014), where the authors studied distributed optimization
for smooth and strongly convex empirical objectives. Compared to Shamir et al. (2014), we do not use any averaging scheme, which would require additional rounds of communication and, moreover, we add an $\ell_1$ regularization term to ensure consistent estimation in high-dimensions. Different from the distributed first-order optimization approaches, the refined objective (4) leverages both global first-order information and local higher-order information. To see this, suppose we set $\lambda_{t+1} = 0$ and that $\mathcal{L}_j(\beta)$ is a quadratic objective with invertible Hessian. Then we have the following closed form solution for (4),

$$\hat{\beta}_{t+1} = \hat{\beta}_t - \left(\nabla^2 \mathcal{L}_1(\hat{\beta}_t)\right)^{-1} \left(m^{-1} \sum_{j \in [m]} \nabla \mathcal{L}_j(\hat{\beta}_t)\right),$$

which is exactly a sub-sampled Newton updating rule. Unfortunately for high-dimensional problems, the Hessian is no longer invertible, and a $\ell_1$ regularization is added to make the solution well behaved. The regularization parameter $\lambda_t$ will be chosen in a way, so that it decreases with the iteration number $t$. As a result we will be able to show that the final estimator performs as well at the centralized formation and local higher-order information. To see this, the refined objective (4) leverages both global first-order information and local higher-order information. To see this, we have

$$\mathcal{L}_j(\hat{\beta}) = \frac{1}{2n} \sum_{i \in [n]} (y_{ji} - \langle x_{ji}, \beta \rangle)^2,$$

where $x_{ji}$ is a subgaussian $p$-dimensional vector of input variables and $\epsilon_{ji}$ is i.i.d. mean zero subgaussian noise. The loss function considered is the usual the squared loss $\ell(y, \hat{y}) = \frac{1}{2}(y - \hat{y})^2$. With this notation, the centralized approach leads to the lasso estimator (Tibshirani, 1996)

$$\hat{\beta}_{\text{centralize}} = \arg\min_{\beta} \frac{1}{m} \sum_{j=1}^{m} \mathcal{L}_j(\beta) + \lambda \|\beta\|_1,$$

where the loss at worker $j$ is

$$\mathcal{L}_j(\beta) = \frac{1}{2n} \sum_{i \in [n]} (y_{ji} - \langle x_{ji}, \beta \rangle)^2.$$

Before stating the main result, we provide the definition of the subgaussian norm (Vershynin, 2012).

**Definition 1 (Subgaussian norm).** The subgaussian norm $\|X\|_{\psi_2}$ of a subgaussian $p$-dimensional random vector $X$, is defined as

$$\|X\|_{\psi_2} = \sup_{x \in \mathbb{R}^{p-1}} \sup_{q > 1} q^{-1/2}(\mathbb{E}[\mathbb{E}[X, x]^q])^{1/q},$$

where $\mathbb{S}^{p-1}$ is the $p$-dimensional unit sphere.

We also need an assumption on the restricted strong convexity constant (Negahban et al., 2012).

**Assumption 2.** We assume that there exists a $\kappa > 0$, such that for any $\Delta \in \mathcal{C}(S, 3)$,

$$\frac{1}{2n} \|X_1 \Delta\|_2^2 \geq \kappa \|\Delta\|_2^2,$$

where

$$\mathcal{C}(S, 3) = \{\Delta \in \mathbb{R}^p \mid \|\Delta_S\|_1 \leq 3\|\Delta_S\|_1\}$$

is a restricted cone in $\mathbb{R}^p$, and $X_1 = [x_{11}^T; x_{12}^T; \ldots; x_{1n}^T] \in \mathbb{R}^{n \times p}$ is the data matrix on the master machine.

When $x_{ji}$ are randomly drawn from a subgaussian distribution, Assumption (2) is satisfied with high probability as long as $n \geq s^2 \log p$ (Rudelson & Zhou, 2013).

We are now ready to state the estimation error bound for $\hat{\beta}_{t+1}$ obtained using Algorithm 1.

**Theorem 3.** Assume that data are generated from a sparse linear regression model in (5) with $\|x_j\|_{\psi_2} \leq \sigma_X$ and $\|\epsilon_{ji}\|_{\psi_2} \leq \sigma$. Let

$$\lambda_{t+1} = \frac{2}{mn} \sum_{j \in [m]} \sum_{i \in [n]} x_{ji} \epsilon_{ji} \|x_{ji}\|_{\psi_2} + 2L \left(\max_{j,i} \|x_{ji}\|_2 \right) \cdot \|\hat{\beta}_t - \beta^*\|_1 \cdot \sqrt{\frac{\log(2p/\delta)}{n}}$$

Then for $t \geq 0$ we have, with probability at least $1 - 2\delta$,

$$\|\hat{\beta}_{t+1} - \beta^*\|_1 \leq \frac{1 - a_{t+1}}{1 - a_n} \frac{4s \sigma_X \log(p/\delta)}{\kappa} \sqrt{\frac{\log(p/\delta)}{mn}} + a_{t+1} \frac{\sigma_X \log(p/\delta)}{\kappa} \sqrt{\frac{\log(p/\delta)}{n}},$$

and

$$\|\hat{\beta}_{t+1} - \beta^*\|_2 \leq \frac{1 - a_{t+1}}{1 - a_n} \frac{12 \sqrt{s} \sigma_X \log(p/\delta)}{\kappa} \sqrt{\frac{\log(p/\delta)}{mn}} + a_{t+1} \frac{b_n \sigma_X \log(p/\delta)}{\kappa} \sqrt{\frac{\log(p/\delta)}{n}},$$

where

$$a_n = \frac{96s \sigma_X \log(p/\delta)}{\kappa} \sqrt{\frac{\log(p/\delta)}{n}}$$

and

$$b_n = \frac{24 \sqrt{s} \sigma_X \log(p/\delta)}{\kappa} \sqrt{\frac{\log(p/\delta)}{n}}.$$

We can simplify the bound obtained in Theorem 3 by looking at the scaling with respect to $n, m, s,$ and $p$, by treating $\kappa, \sigma$ and $\sigma_X$ as constants. Suppose $n \geq s^2 \log p$ and set

$$\lambda_t = \frac{\log p}{mn} + \frac{\log p}{n} \left(s \cdot \frac{\log p}{n}\right)^t.$$
The following error bounds hold for Algorithm 1:

$$\| \hat{\beta}_t - \beta^* \|_1 \leq P s \sqrt{\frac{\log p}{mn}} + \left( s \sqrt{\frac{\log p}{n}} \right)^{t+1}$$

$$\| \hat{\beta}_t - \beta^* \|_2 \leq P \sqrt{\frac{s \log p}{mn}} + \left( s \sqrt{\frac{\log p}{n}} \right) \left( s \sqrt{\frac{\log p}{n}} \right)^{t}.$$  

We can compare the above bounds to the performance of the local and centralized lasso (Wainwright, 2009; Meinshausen & Yu, 2009; Bickel et al., 2009). For \( \hat{\beta}_{\text{local}} \), we have

$$\| \hat{\beta}_{\text{local}} - \beta^* \|_1 \leq P s \sqrt{\frac{\log p}{n}},$$

and

$$\| \hat{\beta}_{\text{local}} - \beta^* \|_2 \leq P \sqrt{\frac{s \log p}{n}}.$$  

For \( \hat{\beta}_{\text{centralize}} \), we have

$$\| \hat{\beta}_{\text{centralize}} - \beta^* \|_1 \leq P s \sqrt{\frac{\log p}{mn}},$$

and

$$\| \hat{\beta}_{\text{centralize}} - \beta^* \|_2 \leq P \sqrt{\frac{s \log p}{mn}}.$$  

We see that after one round of communication, we have

$$\| \hat{\beta}_1 - \beta^* \|_1 \leq P s \sqrt{\frac{\log p}{mn}} + s^2 \frac{\log p}{n},$$

and

$$\| \hat{\beta}_1 - \beta^* \|_2 \leq P \sqrt{\frac{s \log p}{mn}} + s^3 \frac{\log p}{n}. $$

These bounds match the results in Lee et al. (2015b) without expensive debiasing step. Furthermore, when \( m \leq \frac{n \log p}{\log^2 p} \), they match the performance of the centralized lasso. Finally, as long as \( t \geq \log m \) and \( n \geq s^2 \log p \), it is easy to check that \( s \sqrt{\frac{\log p}{n}} \leq s \sqrt{\frac{\log p}{mn}} \). Therefore,

$$\| \hat{\beta}_{t+1} - \beta^* \|_1 \leq P s \sqrt{\frac{\log p}{mn}},$$

and

$$\| \hat{\beta}_{t+1} - \beta^* \|_2 \leq P \sqrt{\frac{s \log p}{mn}},$$

which matches the centralized lasso performance without additional error terms. That is, as long as \( n \geq s^2 \log p \), the rounds of communication to matches centralized procedure only increase logarithmically with the number of machines and independent of other parameters. Differently, for distributed learning methods studied in the literature for minimizing smooth objectives, the rounds of communication to match centralized procedure increase polynomially with \( m \).

(see table 1 in (Zhang & Xiao, 2015)). This is because here we exploit the underlying restricted strong convexity from empirical loss functions, while prior work on distributed minimization of smooth objectives (Shamir et al., 2014; Zhang & Xiao, 2015) only consider strong convexity explicitly from regularization.

4. Generalized Theory and Proof Sketch

In order to establish Theorem 3, we prove an error bound on \( \hat{\beta} - \beta^* \) for a general loss \( \ell(\cdot, \cdot) \) and \( \hat{\beta} \) obtained using Algorithm 1. To simplify the presentation, we assume that the domain \( \mathcal{X} \) is bounded and that the loss function \( \ell(\cdot, \cdot) \) is smooth.

**Assumption 4.** The loss \( \ell(\cdot, \cdot) \) is L-smooth with respect to the second argument:

$$\ell(a, b) - \ell(a, c) \leq L |b - c|, \quad \forall a, b, c \in \mathbb{R}.$$  

Furthermore, \( |\ell'(a, b)| \leq M \) for all \( a, b \in \mathbb{R} \).

Commonly used loss functions in statistical learning, including the squared loss for regression and logistic loss for classification, satisfy this assumption (Zhang et al., 2013b).

Next, we state the restricted strong convexity condition for a general loss function (Negahban et al., 2012).

**Assumption 5.** There exists \( \kappa > 0 \) such that for any \( \Delta \in \mathcal{C}(S, 3) \)

$$\mathcal{L}_1(\beta^* + \Delta) - \mathcal{L}_1(\beta^* - \langle \nabla \mathcal{L}_1(\beta^*), \Delta \rangle) \geq \kappa \|\Delta\|^2,$$

with \( \mathcal{C}(S, 3) = \{ \Delta \in \mathbb{R}^p : \| \Delta_{S^c} \|_1 \leq 3 \| \Delta_S \|_1 \} \).

The restricted strong convexity holds with high probability for a wide range of models and designs and it is commonly assumed for showing consistent estimation in high-dimensional (see, for example, van de Geer & Bühlmann, 2009; Negahban et al., 2012; Raskutti et al., 2010; Rudelson & Zhou, 2013, for details).

Our main theoretical result establishes a recursive estimation error bound, which relates the estimation error \( \| \hat{\beta}_{t+1} - \beta^* \| \) to that of the previous iteration \( \| \hat{\beta}_t - \beta^* \| \).

**Theorem 6.** Suppose Assumption 4 and 5 holds. Let

$$\lambda_{t+1} = 2\left( \frac{1}{m} \sum_{j \in [m]} \nabla \mathcal{L}_j(\beta^*) \right)_{\ell_2} + 2 L \left( \max_{j,i} \| x_{j,i} \|_{\ell_2}^2 \right) \| \beta^* - \hat{\beta}_t \|_1 \sqrt{\frac{\log(2p/\delta)}{n}} + 2 M \left( \max_{j,i} \| x_{j,i} \|_{\ell_2} \right) \left( \| \hat{\beta}_t - \beta^* \|_2^2 \right).$$  

(9)
Then with probability at least $1 - \delta$, we have
\[
\| \hat{\beta}_{t+1} - \beta^* \|_1 \leq \frac{48s}{\kappa} \left\| \frac{1}{m} \sum_{j \in [m]} \nabla L_j (\beta^*) \right\|_x + \frac{48sL}{\kappa} \left( \max_{j,i} |x_{ji}|^2 \right) \| \beta^* - \tilde{\beta}_t \|_1 \left\{ \frac{\log(2p/\delta)}{n} \right\} + \frac{48sM}{\kappa} \left( \max_{j,i} |x_{ji}|^3 \right) \left( \| \tilde{\beta}_t - \beta^* \|_1^2 \right),
\]
and
\[
\| \hat{\beta}_{t+1} - \beta^* \|_2 \leq \frac{12\sqrt{s}}{\kappa} \left\| \frac{1}{m} \sum_{j \in [m]} \nabla L_j (\beta^*) \right\|_x + \frac{12\sqrt{s}L}{\kappa} \left( \max_{j,i} |x_{ji}|^2 \right) \| \beta^* - \tilde{\beta}_t \|_1 \left\{ \frac{\log(2p/\delta)}{n} \right\} + \frac{12\sqrt{s}M}{\kappa} \left( \max_{j,i} |x_{ji}|^3 \right) \left( \| \tilde{\beta}_t - \beta^* \|_1^2 \right).
\]

Theorem 6 upper bounds the estimation error $\| \hat{\beta}_{t+1} - \beta^* \|_1$ as a function of $\| \hat{\beta}_t - \beta^* \|_1$. Applying Theorem 6 iteratively, we immediately obtain the following estimation error bound which depends on the quality of local $\ell_1$ regularized estimation $\| \hat{\beta}_0 - \beta^* \|_1$.

**Corollary 7.** Suppose the conditions of Theorem 6 are satisfied. Furthermore, suppose that for all $t$, we have
\[
M \left( \max_{j,i} |x_{ji}| \right) \| \hat{\beta}_t - \beta^* \|_1 \leq L \sqrt{\frac{\log(2p/\delta)}{n}}. \tag{10}
\]
Then with probability at least $1 - \delta$, we have
\[
\| \hat{\beta}_{t+1} - \beta^* \|_1 \leq a_{t+1} \| \hat{\beta}_0 - \beta^* \|_1 + (1 - a_{t+1})^{-1} \left( 1 - a_{t+1} \right) \cdot \frac{48s}{\kappa} \left\| \frac{1}{m} \sum_{j \in [m]} \nabla L_j (\beta^*) \right\|_x
\]
and
\[
\| \hat{\beta}_{t+1} - \beta^* \|_2 \leq b_{t+1} \cdot \| \hat{\beta}_0 - \beta^* \|_1 + (1 - a_{t+1})^{-1} \left( 1 - a_{t+1} \right) \cdot \frac{12\sqrt{s}}{\kappa} \left\| \frac{1}{m} \sum_{j \in [m]} \nabla L_j (\beta^*) \right\|_x,
\]
where
\[
a_{t+1} = \frac{96sL}{\kappa} \left( \max_{j,i} |x_{ji}| \right) \sqrt{\frac{\log(2p/\delta)}{n}}
\]
and
\[
b_{t+1} = \frac{24\sqrt{s}L}{\kappa} \left( \max_{j,i} |x_{ji}| \right) \sqrt{\frac{\log(2p/\delta)}{n}}.
\]

For the quadratic loss we have that $M = 0$ and the condition in (10) holds. For other types of losses, condition in (10) will be true for $t$ large enough when $m \geq s^2$, leading to local exponential rate of convergence until reaching statistical optimal region.

### 4.1. Proof Sketch of Theorem 6

We first analyze how the estimation error bound decreases after one round of communication. In particular, we bound $\| \hat{\beta}_{t+1} - \beta^* \|_1$ with $\| \tilde{\beta}_t - \beta^* \|_1$. Define
\[
\tilde{L}_1 (\beta, \tilde{\beta}_t) = L_1 (\beta) + \frac{1}{m} \sum_{j \in [m]} \nabla L_j (\tilde{\beta}_t) - \nabla L_1 (\beta),
\]
Then
\[
\nabla \tilde{L}_1 (\beta, \tilde{\beta}_t) = \nabla L_1 (\beta) + \frac{1}{m} \sum_{j \in [m]} \nabla L_j (\tilde{\beta}_t) - \nabla L_1 (\tilde{\beta}_t).
\]

The following lemma bounds the $\ell_1$ norm of $\nabla \tilde{L}_1 (\beta, \tilde{\beta}_t)$.

**Lemma 8.** With probability at least $1 - \delta$, we have
\[
\| \nabla \tilde{L}_1 (\beta, \tilde{\beta}_t) \|_1 \leq \frac{1}{m} \sum_{j \in [m]} \| \nabla L_j (\beta^*) \|_x + 2L \left( \max_{j,i} |x_{ji}|^2 \right) \| \beta^* - \tilde{\beta}_t \|_1 \frac{\log(2p/\delta)}{n} + M \left( \max_{j,i} |x_{ji}|^3 \right) \left( \| \tilde{\beta}_t - \beta^* \|_1^2 \right).
\]

The lemma bounds the magnitude of the gradient of the loss at optimum point $\beta^*$. This will be used to guide our choice of the $\ell_1$ regularization parameter $\lambda_{t+1}$ in (4). The following lemma shows that as long as $\lambda_{t+1}$ is large enough, it is guaranteed that $\tilde{\beta}_{t+1} - \beta^*$ is in a restricted cone.

**Lemma 9.** Suppose
\[
\lambda_{t+1}/2 \geq \| \nabla \tilde{L}_1 (\beta^*, \beta^*_t) \|_x.
\]
Then with probability at least $1 - \delta$, we have $\tilde{\beta}_{t+1} - \beta^* \in C(S, 3)$.

Based on the conic condition and restricted strong convexity condition, we can obtain the recursive error bound stated in Theorem 6 following the proof strategy as in Negahban et al. (2012).

**Applications** Theorem 6 can be used to establish statistical guarantees for more general sparse learning problems, for example consider the logistic regression is a popular classification model where the binary label $y_{ji} \in \{-1, 1\}$ is drawn according to a Bernoulli distribution:
\[
P(y_{ji} = \pm 1 | x_{ji}) = \frac{\exp(y_{ji} x_{ji}, \beta^*)}{\exp(y_{ji} x_{ji}, \beta^*) + 1}, \tag{12}
\]
we can establish local exponential convergence when applying Algorithm 1 to estimate $\beta^*$ in the high-dimensional logistic model. Section A in Appendix provide formal guarantees and more illustrative examples.

5. Experiments

In this section we present empirical comparisons between various approaches on both simulated and real world datasets\(^3\). We run the algorithms for both distributed regression and classification problems, and compare with the following algorithms: i) Local; ii) Centralize; iii) Distributed proximal gradient descent (Prox GD); iv) Avg-Debias (Lee et al., 2015b) with hard thresholding, and v) the proposed EDSL approach.

5.1. Simulations

We first examine the algorithms on simulated data. We generate $\{x_{ij}\}_{j \in [m], i \in [n]}$ from a multivariate normal distribution with mean zero and covariance matrix $\Sigma$. The covariance $\Sigma$ controls the condition number of the problem and we will varying it to see how the performance changes. We set $\Sigma_{ij} = 0.5^{i-j}$ for the well-conditioned setting and $\Sigma_{ij} = 0.5^{i-j}/5$ for the ill-conditioned setting. The response variable $\{y_{ij}\}_{j \in [m], i \in [n]}$ are drawn from (5) and (12) for regression and classification problems, respectively. For regression, the noise $\epsilon_{ij}$ is sampled from a standard normal distribution. The true model $\beta^*$ is set to be $s$-sparse, where the first $s$-entries are sampled i.i.d. from a uniform distribution in $[0, 1]$, and the other entries are set to zero.

We run experiments with various $(n, p, m, s)$ settings\(^4\). The estimation error $||\hat{\beta}_i - \beta^*||_2$ is shown versus rounds of communications for for Prox GD and the proposed EDSL algorithm. We also plot the estimation error of Local, Avg-Debias, and Centralize as horizontal lines, since the communication cost is fixed for these algorithms\(^5\). Figure 1 summarize the results, averaged across 10 independent trials. We have the following observations:

- The Avg-Debias approach obtained much better estimation error compared to Local after one round of communication and sometimes performed quite close to Centralize. However, in most cases, there is still a gap compared with Centralize, especially when the problem is not well-conditioned or $m$ is large.
- ProxGD converges very slow when the condition number becomes bad ($\Sigma_{ij} = 0.5^{i-j}/5$ case).
- As theory suggests, EDSL obtained a solution that is

\(^3\)Please refer to Section C in Appendix for full experimental results and more details.

\(^4\)n: sample size per machine, p: problem dimension, m: number of machines, s: true support size.

\(^5\)these algorithms have zero, one-shot and full communications, respectively.

\(^6\)To give some senses about computational cost, for a problem with $n = 200, p = 1000$, at each round EDSL takes about 0.048s, while Avg-Debias takes about 40.334s.
Efficient Distributed Learning with Sparsity

Rounds of Communications

Figure 2. Comparison of various approaches for distributed sparse regression and classification on real world datasets.

Above experiments illustrate our theoretical results in finite samples. As suggested by theory, when sample size per machine $n$ is relatively small, one round of communication is not sufficient to make Avg-Debias matches the performance of centralized procedure. However, EDSL could match the performance of Avg-Debias with one round of communication and further improve the estimation quality by exponentially reducing the gap between centralized procedure with Avg-Debias, until matching the centralized performance. Thus, the proposed EDSL improves the Avg-Debias approach both computationally and statistically.

5.2. Real-world Data Evaluation

In this section, we compare the distributed sparse learning algorithms on several real world datasets. For all data sets, we use 60% of data for training, 20% as held-out validation set for tuning the parameters, and the remaining 20% for testing. We randomly partition data 10 times and report the average performance on the test set. For regression tasks, the evaluation metric is the normalized Mean Squared Error (normalized MSE), while for classification tasks we report the miss-classification error. We randomly partition the data on $m=10$ machines. A subset of the results are plotted in Figure 2 where for some data sets the performance of Avg-Debias is significantly worse than others (mostly because the debiasing step fails), thus we omit these plots.

Since there is no well-specified model on these datasets, the curves behave quite differently on different data sets. However, a large gap between the local and centralized procedure is consistent as the later uses 10 times more data. Avg-Debias often fails on these real datasets and performs much worse than in the simulations, the main reason might be that the assumptions, such as well-specified model or generalized coherence condition, fail, then Avg-Debias can totally fail and produce solution even much worse than the local. Nevertheless, the proposed EDSL performs quite robust on real world data sets, and can often output a solution which is highly competitive with the centralized model within a few rounds of communications. We also observed a slight “zig-zag” behavior for EDSL approach on some data sets. For example, on the mushrooms data set, the predictive performance of EDSL is not stable. In sum, the experimental results on real world data sets verified that the proposed EDSL method is effective for distributed sparse learning problems.

6. Conclusion and Discussion

We proposed a novel approach for distributed learning with sparsity, which is efficient in both computation and communication. Our theoretical analysis showed that the proposed method works under weaker conditions than Avg-Debias estimator while matches its error bound with one-round communication. Furthermore, the estimation error can be improved with a logarithmic more rounds of communication until matching the centralized procedure. Experiments on both simulated and real-world data demonstrate that the proposed method significantly improves the performance over one shot averaging approaches, and matches the centralized procedure with few iterations.

There might be several ways to improve this work. As we see in real data experiments, the proposed approach can still perform slightly worse than the centralized approach on certain datasets. It is interesting to explore how to make EDSL provably work under even weaker assumptions. For example, EDSL requires $O(s^2 \log p)$ samples per machine to match the centralized method in $O(\log m)$ rounds of communications, however, it is not clear whether the sample size requirement can be improved, while still maintaining low-communication cost. Last but not the least, it is interesting to explore presented ideas to improve the computational cost of communication-efficient distributed multi-task learning with shared support (Wang et al., 2015).
