Alternating Randomized Block Coordinate Descent

Jelena Diakonikolas 1  Lorenzo Orecchia 1

Abstract
Block-coordinate descent algorithms and alternating minimization methods are fundamental optimization algorithms and an important primitive in large-scale optimization and machine learning. While various block-coordinate-descent-type methods have been studied extensively, only alternating minimization—which applies to the setting of only two blocks—is known to have convergence time that scales independently of the least smooth block. A natural question is then: is the setting of two blocks special? We show that the answer is “no” as long as the least smooth block can be optimized exactly—an assumption that is also needed in the setting of alternating minimization. We do so by introducing a novel algorithm AR-BCD, whose convergence time scales independently of the least smooth (possibly non-smooth) block. The basic algorithm generalizes both alternating minimization and randomized block coordinate (gradient) descent, and we also provide its accelerated version—AAR-BCD.

1. Introduction
First-order methods for minimizing smooth convex functions are a cornerstone of large-scale optimization and machine learning. Given the size and heterogeneity of the data in these applications, there is a particular interest in designing iterative methods that, at each iteration, only optimize over a subset of the decision variables (Wright, 2015).

This paper focuses on two classes of methods that constitute important instantiations of this idea. The first class is that of block-coordinate descent methods, i.e., methods that partition the set of variables into $n \geq 2$ blocks and perform a gradient descent step on a single block at every iteration, while leaving the remaining variable blocks fixed. A paradigmatic example of this approach is the randomized Kaczmarz algorithm of (Strohmer & Vershynin, 2009) for linear systems and its generalization (Nesterov, 2012). The second class is that of alternating minimization methods, i.e., algorithms that partition the variable set into only $n = 2$ blocks and alternate between exactly optimizing one block or the other at each iteration (see, e.g., (Beck, 2015) and references therein).

Besides the computational advantage in only having to update a subset of variables at each iteration, methods in these two classes are also able to exploit better the structure of the problem, which, for instance, may be computationally expensive only in a small number of variables. To formalize this statement, assume that the set of variables is partitioned into $n \leq N$ mutually disjoint blocks, where the $i^{\text{th}}$ block of variable $x$ is denoted by $x^i$, and the gradient corresponding to the $i^{\text{th}}$ block is denoted by $\nabla_i f(x)$. Each block $i$ will be associated with a smoothness parameter $L_i$, i.e., $\forall x, y \in \mathbb{R}^N$:

$$\|\nabla_i f(x + I^i_k y) - \nabla_i f(x)\| \leq L_i \|y\|, \quad (1.1)$$

where $I^i_k$ is a diagonal matrix whose diagonal entries equal one for coordinates from block $i$, and are zero otherwise.

In this setting, the convergence time of standard randomized block-coordinate descent methods, such as those in (Nesterov, 2012), scales as $O\left(\frac{\sum L_i}{\epsilon}\right)$, where $\epsilon$ is the desired additive error. By contrast, when $n = 2$, the convergence time of the alternating minimization method (Beck, 2015) scales as $O\left(\frac{L_{\min}}{\epsilon}\right)$, where $L_{\min}$ is the minimum smoothness parameter of the two blocks. This means that one of the two blocks can have arbitrarily poor smoothness (including $\infty$), as long as it is easy to optimize over it. Some important examples with a nonsmooth block (with smoothness parameter equal to infinity) can be found in (Beck, 2015). Additional examples of problems for which exact optimization over the least smooth block can be performed efficiently are provided in Appendix B.

In this paper, we address the following open question, which was implicitly raised by (Beck & Tetruashvili, 2013): can we design algorithms that combine the features of randomized block-coordinate descent and alternating minimization? In particular, assuming we can perform ex-
We answer these questions in the affirmative by presenting a block-coordinate descent algorithm whose running time scales with \(O(\sum_{i=1}^{n} L_i)\), i.e., independently of the smoothness \(L_n\) of the \(n^{th}\) block? This would generalize both existing block-coordinate descent methods, by allowing one block to be optimized exactly, and existing alternating minimization methods, by allowing \(n\) to be larger than 2 and requiring exact optimization only on a single block.

We answer these questions in the affirmative by presenting a novel algorithm: alternating randomized block coordinate descent (AR-BCD). The algorithm alternates between an exact optimization over a fixed, possibly non-smooth block, and a gradient descent or exact optimization over a randomly selected block among the remaining blocks. For two blocks, the method reduces to the standard alternating minimization, while when the non-smooth block is empty (not optimized over), we get randomized block coordinate descent (RCDM) from (Nesterov, 2012).

Our second contribution is AAR-BCD, an accelerated version of AR-BCD, which achieves the accelerated rate of \(\frac{1}{\sqrt{n}}\) without incurring any dependence on the smoothness of block \(n\). Furthermore, when the non-smooth block is empty, AAR-BCD recovers the fastest known convergence bounds for block-coordinate descent (Qu & Richtárik, 2016; Allen-Zhu et al., 2016; Nesterov, 2012; Lin et al., 2014; Nesterov & Stich, 2017). Another conceptual contribution is our extension of the approximate duality gap technique of (Diakonikolas & Orecchia, 2017), which leads to a general and more streamlined analysis. Finally, to illustrate the results, we perform a preliminary experimental evaluation of our methods against existing block-coordinate algorithms and discuss how their performance depends on the smoothness and size of the blocks.

**Related Work** Alternating minimization and cyclic block coordinate descent are old and fundamental algorithms (Ortega & Rheinboldt, 1970) whose convergence (to a stationary point) has been studied even in the non-convex setting, in which they were shown to converge asymptotically under the additional assumptions that the blocks are optimized exactly and their minimizers are unique (Bertsekas, 1999). However, even in the non-smooth convex case, methods that perform exact minimization over a fixed set of blocks may converge arbitrarily slowly. This has led scholars to focus on the case of smooth convex minimization, for which nonasymptotic convergence rates were obtained recently in (Beck & Tetruashvili, 2013; Beck, 2015; Sun & Hong, 2015; Saha & Tewari, 2013). However, prior to our work, convergence bounds that are independent of the largest smoothness parameter were only known for the setting of two blocks.

Randomized coordinate descent methods, in which steps over coordinate blocks are taken in a non-cyclic randomized order (i.e., in each iteration one block is sampled with replacement) were originally analyzed in (Nesterov, 2012). The same paper (Nesterov, 2012) also provided an accelerated version of these methods. The results of (Nesterov, 2012) were subsequently improved and generalized to various other settings (such as, e.g., composite minimization) in (Lee & Sidford, 2013; Allen-Zhu et al., 2016; Nesterov & Stich, 2017; Richtárik & Takáč, 2014; Fercoq & Richtárik, 2015; Lin et al., 2014). The analysis of the different block coordinate descent methods under various sampling probabilities (that, unlike in our setting, are non-zero over all the blocks) was unified in (Qu & Richtárik, 2016) and extended to a more general class of steps within each block in (Gower & Richtárik, 2015; Qu et al., 2016).

Our results should be carefully compared to a number of proximal block-coordinate methods that rely on different assumptions (Tseng & Yun, 2009; Richtárik & Takáč, 2014; Lin et al., 2014; Fercoq & Richtárik, 2015). In this setting, the function \(f\) is assumed to have the structure \(f_0(x) + \Psi(x)\), where \(f_0\) is smooth, the non-smooth convex function \(\Psi\) is separable over the blocks, i.e., \(\Psi(x) = \sum_{i=1}^{n} \Psi_i(x_i)\), and we can efficiently compute the proximal operator of each \(\Psi_i\). This strong assumption allows these methods to make use of the standard proximal optimization framework. By contrast, in our paper, the convex objective can be taken to have an arbitrary form, where the non-smoothness of a block need not be separable, though the function is assumed to be differentiable.

### 2. Preliminaries

We assume that we are given oracle access to the gradients of a continuously differentiable convex function \(f : \mathbb{R}^N \rightarrow \mathbb{R}\), where computing gradients over only a subset of coordinates is computationally much cheaper than computing the full gradient. We are interested in minimizing \(f(\cdot)\) over \(\mathbb{R}^N\), and we denote \(x_* = \text{argmin}_{x \in \mathbb{R}^N} f(x)\). We let \(\| \cdot \|\) denote an arbitrary (but fixed) norm, and \(\| \cdot \|_d\) denote its dual norm, defined in the standard way: 
\[
\|z\|_d = \text{sup}_{x \in \mathbb{R}^N : \|x\| = 1} \langle z, x \rangle.
\]

Let \(I_N\) be the identity matrix of size \(N\), \(I_N^j\) be a diagonal matrix whose diagonal elements \(j\) are equal to one if variable \(j\) is in the \(i^{th}\) block, and zero otherwise. Notice that \(I_N = \sum_{i=1}^{N} I_N^i\). Let \(S_i(x) = \{y \in \mathbb{R}^N : (I_N - I_N^i)y = (I_N - I_N^i)x\}\), that is, \(S_i\) contains all the points from \(\mathbb{R}^N\) whose coordinates differ from those of \(x\) only over block \(i\).

We denote the smoothness parameter of block \(i\) by \(L_i\), as

\[L_i \equiv \text{smoothness of coordinate block } i\]
defined in Equation (1.1). Equivalently, \( \forall \mathbf{x}, \mathbf{y} \in \mathbb{R}^N \):

\[
f(\mathbf{x} + I_n^i \mathbf{y}) \leq f(\mathbf{x}) + \langle \nabla_i f(\mathbf{x}), \mathbf{y} \rangle + \frac{L_i}{2} \| \mathbf{y} \|^2. \tag{2.1}
\]

The gradient step over block \( i \) is then defined as:

\[
T_i(\mathbf{x}) = \arg\min_{\mathbf{y} \in S_i(\mathbf{x})} \left\{ \langle \nabla f(\mathbf{x}), \mathbf{y} - \mathbf{x} \rangle + \frac{L_i}{2} \| \mathbf{y} - \mathbf{x} \|^2 \right\}. \tag{2.2}
\]

By standard arguments (see, e.g., Exercise 3.27 in (Boyd & Vandenberghe, 2004)):

\[
f(T_i(\mathbf{x})) - f(\mathbf{x}) \leq -\frac{1}{2L_i} \| \nabla_i f(\mathbf{x}) \|^2. \tag{2.3}
\]

Without loss of generality, we will assume that the \( n^{th} \) block has the largest smoothness parameter and is possibly non-smooth (i.e., it can be \( L_n = \infty \)). The standing assumption is that exact minimization over the \( n^{th} \) block is "easy", meaning that it is computationally inexpensive and possibly solvable in closed form; for some important examples that have this property, see Appendix B. Observe that when block \( n \) contains a small number of variables, it is often computationally inexpensive to use second-order optimization methods, such as, e.g., interior point method.

We assume that \( f(\cdot) \) is strongly convex with parameter \( \mu \geq 0 \), where it could be \( \mu = 0 \) (in which case \( f(\cdot) \) is not strongly convex). Namely, \( \forall \mathbf{x}, \mathbf{y} \):

\[
f(\mathbf{y}) \geq f(\mathbf{x}) + \langle \nabla f(\mathbf{x}), \mathbf{y} - \mathbf{x} \rangle + \frac{\mu}{2} \| \mathbf{y} - \mathbf{x} \|^2. \tag{2.4}
\]

When \( \mu > 0 \), we take \( \| \cdot \| = \| \cdot \|_2 \), which is customary for smooth and strongly convex minimization (Bubeck, 2014).

Throughout the paper, whenever we take unconditional expectation, it is with respect to all randomness in the algorithm.

### 2.1. Alternating Minimization

In (standard) alternating minimization (AM), there are only two blocks of coordinates, i.e., \( n = 2 \). The algorithm is defined as follows.

\[
\hat{x}_k = \arg\min_{\mathbf{x} \in S_1(x_{k-1})} f(\mathbf{x}), \quad x_k = \arg\min_{\mathbf{x} \in S_2(x_k)} f(\mathbf{x}), \tag{AM}
\]

\( x_1 \in \mathbb{R}^N \) is an arbitrary initial point.

We note that for the standard analysis of alternating minimization (Beck, 2015), the exact minimization step over the smoother block can be replaced by a gradient step (Equation (2.2)), while still leading to convergence that is only dependent on the smaller smoothness parameter.

### 2.2. Randomized Block Coordinate (Gradient) Descent

The simplest version of randomized block coordinate (gradient) descent (RCDM) can be stated as (Nesterov, 2012):

Select \( i_k \in \{1, \ldots, n\} \) w.p. \( p_{i_k} > 0 \),

\[
x_k = T_{i_k}(x_{i_k-1}), \quad \text{(RCDM)}
\]

\( x_1 \in \mathbb{R}^N \) is an arbitrary initial point,

where \( \sum_{i=1}^n p_i = 1 \). A standard choice of the probability distribution is \( p_i \sim L_i \), leading to the convergence rate that depends on the sum of block smoothness parameters.

### 3. AR-BCD

The basic version of alternating randomized block coordinate descent (AR-BCD) is a direct generalization of (AM) and (RCDM): when \( n = 2 \), it is equivalent to (AM), while when the size of the \( n^{th} \) block is zero, it reduces to (RCDM). The method is stated as follows:

Select \( i_k \in \{1, \ldots, n-1\} \) w.p. \( p_{i_k} > 0 \),

\[
\hat{x}_k = T_{i_k}(x_{i_k-1}), \quad x_k = \arg\min_{\mathbf{x} \in S_k(x_k)} f(\mathbf{x}), \tag{AR-BCD}
\]

\( x_1 \in \mathbb{R}^N \) is an arbitrary initial point,

where \( \sum_{i=1}^{n-1} p_i = 1 \). We note that nothing will change in the analysis if the step \( \hat{x}_k = T_{i_k}(x_{i_k-1}) \) is replaced by \( \hat{x}_k = \arg\min_{\mathbf{x} \in S_k(x_{i_k-1})} f(\mathbf{x}) \), since \( \min_{\mathbf{x} \in S_k(x_{i_k-1})} f(\mathbf{x}) \leq f(T_{i_k}(x_{i_k-1})) \).

In the rest of the section, we show that (AR-BCD) leads to a convergence bound that interpolates between the convergence bounds of (AM) and (RCDM): it depends on the sum of the smoothness parameters of the first \( n-1 \) blocks, while the dependence on the remaining problem parameters is the same for all these methods.

### 3.1. Approximate Duality Gap

To analyze (AR-BCD), we extend the approximate duality gap technique (Diakonikolas & Orecchia, 2017) to the setting of randomized block coordinate descent methods. The approximate duality gap \( G_k \) is defined as the difference of an upper bound \( U_k \) and a lower bound \( L_k \) to the minimum function value \( f(x_*) \). For (AR-BCD), we choose the upper bound to simply be \( U_k = f(x_{k-1}) \).

The generic construction of the lower bound is as follows. Let \( x_1, x_2, \ldots, x_k \) be any sequence of points from \( \mathbb{R}^N \) (in fact we will choose them to be exactly the sequence constructed by (AR-BCD)). Then, by (strong) convexity of \( f(\cdot) \), \( f(x_j) \geq f(x_i) + \langle \nabla f(x_i), x_j - x_i \rangle + \frac{L_k}{2} \| x_j - x_i \|^2 \), \( \forall j \in \{1, \ldots, k\} \). In particular, if \( a_j > 0 \) is a sequence...
of (deterministic, independent of $i$) positive real numbers and $A_k = \sum_{j=1}^k a_j$, then:

$$f(x_*) \geq \sum_{j=1}^k a_j f(x_j) + \sum_{j=1}^k a_j (\nabla f(x_j), x_* - x_j)$$

$$+ \frac{\mu}{2} \sum_{j=1}^k a_j \|x_* - x_j\|^2 \overset{\text{def}}{=} L_k. \tag{3.1}$$

### 3.2. Convergence Analysis

The main idea in the analysis is to show that $E[A_k G_k - A_{k-1} G_{k-1}] \leq E_k$, for some deterministic $E_k$. Then, using linearity of expectation, $E[f(x_{k+1})] - f(x_*) \leq E[A_k G_k] + \sum_{i=1}^k E_i$. The bound in expectation can then be turned into a bound in probability, using well-known concentration bounds. The main observation that allows us not to pay for the non-smooth block is:

**Observation 3.1.** For $x_k$'s constructed by (AR-BCD), $\nabla_n f(x_0) = 0, \forall k$, where $0$ is the vector of all zeros.

This observation is essentially what allows us to sample $i_k$ only from the first $n-1$ blocks, and holds due to the step $x_k = \arg\min_{x \in S_n(x_k)} f(x)$ from (AR-BCD).

Denote $R_{x_k} = \max_{x \in \mathbb{R}^n} \{\|f'_{i_k}(x_* - x)\|^2 : f(x) \leq f(x_1)\}$, and let us bound the initial gap $A_1 G_1$.

**Proposition 3.2.** $E[A_1 G_1] \leq E_1$, where $E_1 = a_1 \sum_{i=1}^{n-1} \left(\frac{L_i}{2p_i} + \frac{\mu}{2}\right) R_{x_*}^i.$

**Proof.** By linearity of expectation, $E[A_1 G_1] = E[A_1 U_1] - E[A_1 L_1]$. The initial lower bound is deterministic, and, by $\nabla_n f(x_1) = 0$ and duality of norms, is bounded as:

$$E[A_1 L_1] \geq a_1 f(x_1) - a_1 \sum_{i=0}^{n-1} \|\nabla_i f(x_1)\| \|x_* - x_i\|$$

$$+ a_1 \frac{\mu}{2} \|x_* - x_1\|^2.$$

Using (2.3), if $i_2 = i$, then:

$$U_1 = f(x_2) \leq f(x_2) \leq f(x_1) - \frac{1}{2L_i} \|\nabla_i f(x_1)\|^2.$$

Since block $i$ is selected with probability $p_i$ and $A_1 = a_1$:

$$E[A_1 U_1] \leq a_1 f(x_1) - a_1 \sum_{i=1}^{n-1} a_1 p_i \|\nabla_i f(x_1)\|^2.$$

Since the inequality $2a b - a^2 \leq b^2$ holds $\forall a, b$, we have:

$$a_1 \|\nabla_i f(x_1)\| \|x_* - x_i\| \leq a_1 \frac{L_i}{2p_i} \|x_* - x_i\|^2, \forall i \in \{1, \ldots, n - 1\}.$$

Hence, when $\mu = 0$, $E[A_1 G_1] \leq \sum_{i=1}^{n-1} \frac{a_1 L_i}{2p_i} \|x_* - x_i\|^2.$

When $\mu > 0$, since in that case we are assuming $\|x_* - x_1\| \geq \sum_{i=1}^{n-1} \|x_* - x_i\|^2$, leading to $E[A_1 G_1] \leq a_1 \sum_{i=1}^{n-1} \left(\frac{L_i}{2p_i} + \frac{\mu}{2}\right) \|x_* - x_i\|^2.$

We now show how to bound the error in the decrease of the scaled gap $A_k G_k$.

**Lemma 3.3.** $E[A_k G_k - A_{k-1} G_{k-1}] \leq E_k$, where $E_k = a_k \sum_{i=1}^{n-1} \left(\frac{L_i}{2a_k p_i} + \frac{\mu}{2}\right) R_{x_*}^i.$

**Proof.** Let $F_k$ denote the natural filtration up to iteration $k$.

By linearity of expectation and $A_k L_k - A_{k-1} L_{k-1}$ being measurable w.r.t. $F_k$,

$$E[A_k G_k - A_{k-1} G_{k-1} | F_k]$$

$$= E[A_k U_k - A_{k-1} U_{k-1} | F_k] - (A_k L_k - A_{k-1} L_{k-1}).$$

With probability $p_i$ and as $f(x_{k+1}) \leq f(x_{k+1})$, the change in the upper bound is:

$$A_k U_k - A_{k-1} U_{k-1} \leq A_k f(\hat{x}_{k+1}) - A_{k-1} f(x_k)$$

$$\leq a_k f(x_k) - A_k \frac{\mu}{2L_i} \|\nabla_i f(x_k)\|^2,$$

where the second line follows from $\hat{x}_{k+1} = T_{i_k}(x_k)$ and Equation (2.3). Hence:

$$E[A_k U_k - A_{k-1} U_{k-1} | F_k]$$

$$\leq a_k f(x_k) - A_k \sum_{i=1}^{n-1} \frac{p_i}{2L_i} \|\nabla_i f(x_k)\|^2.$$

On the other hand, using the duality of norms, the change in the lower bound is:

$$A_k L_k - A_{k-1} L_{k-1}$$

$$\geq a_k f(x_k) - a_k \sum_{i=1}^{n-1} \|\nabla_i f(x_k)\| \|x_* - x_i\|$$

$$+ a_k \frac{\mu}{2} \|x_* - x_1\|^2$$

$$\geq a_k f(x_k) - a_k \sum_{i=1}^{n-1} \|\nabla_i f(x_k)\| \sqrt{R_{x_*}^i}$$

$$+ a_k \frac{\mu}{2} \|x_* - x_1\|^2.$$

By the same argument as in the proof of Proposition 3.2, it follows that: $E[A_k G_k - A_{k-1} G_{k-1} | F_k] \leq a_k \sum_{i=1}^{n-1} \left(\frac{L_i a_k}{2a_k p_i} + \frac{\mu}{2}\right) R_{x_*}^i = E_k$. Taking expectations on both sides, as $E_k$ is deterministic, the proof follows.

We are now ready to prove the convergence bound for (AR-BCD), as follows.

**Theorem 3.4.** Let $x_k$ evolve according to (AR-BCD). Then, $\forall k \geq 1$: 
1. If \( \mu = 0 \) : \( \mathbb{E}[f(x_{k+1})] - f(x_*) \leq \frac{2}{k+3} \sum_{i=1}^{n-1} \frac{L_i}{L_{i'}} R_{x_i}^2 \). In particular, for \( p_i = \frac{L_i}{\sum_{i'=1}^{n} L_{i'}} \), 1 \( \leq i \leq n - 1 \):
\[
\mathbb{E}[f(x_{k+1})] - f(x_*) \leq \frac{2(\sum_{i'=1}^{n-1} L_{i'}) \sum_{i=1}^{n-1} R_{x_i}^2}{k+3}.
\]
Similarly, for \( p_i = \frac{1}{n-1} \), 1 \( \leq i \leq n - 1 \) :
\[
\mathbb{E}[f(x_{k+1})] - f(x_*) \leq \frac{2(n-1) \sum_{i=1}^{n-1} L_i R_{x_i}}{k+3}.
\]
2. If \( \mu > 0 \), \( p_i = \frac{L_i}{\sum_{i'=1}^{n} L_{i'}} \) and \( \| \cdot \| = \| \cdot \|_2 \):
\[
\mathbb{E}[f(x_{k+1})] - f(x_*) \leq \left(1 - \frac{\mu}{\sum_{i'=1}^{n-1} L_{i'}} \right)^k \cdot \frac{\left(\sum_{i'=1}^{n-1} L_{i'}\right) \| (f_N - f_N^k)(x_* - x_1) \|^2}{2}.
\]

Proof. From Proposition 3.2 and Lemma 3.3, by linearity of expectation and the definition of \( G_k \):
\[
\mathbb{E}[f(x_{k+1})] - f(x_*) \leq \mathbb{E}[G_k] \leq \frac{\sum_{j=1}^{k} E_j}{A_k}, \quad (3.2)
\]
where \( E_j = \frac{a_j^2}{A_j} \sum_{i=1}^{n-1} \frac{L_i}{2p_i} R_{x_i}^2 \). Notice that the algorithm does not depend on the sequence \( \{a_j\} \) and thus we can choose it arbitrarily. Suppose that \( \mu = 0 \). Let \( a_j = \frac{j+1}{2A_j} \). Then \( a_j^2 = \frac{(j+1)^2}{4A_j^2} \leq 1 \), and thus:
\[
\frac{\sum_{j=1}^{k} E_j}{A_k} \leq \frac{2\sum_{i=1}^{n-1} L_{i'} R_{x_i}}{k+3},
\]
which proves the first part of the theorem, up to concrete choices of \( p_i \)'s, which follow by simple computations.

For the second part of the theorem, as \( \mu > 0 \), we are assuming that \( \| \cdot \| = \| \cdot \|_2 \), as discussed in Section 2. From Lemma 3.3, \( E_j = a_j \sum_{i=1}^{n-1} \left( \frac{L_i}{2A_j p_i} - \frac{\mu}{A_j} \right) R_{x_i}^2 \). As \( p_i = \frac{L_i}{\sum_{i'=1}^{n} L_{i'}} \), if we take \( a_j = \frac{\mu}{A_j} \sum_{i'=1}^{n} L_{i'} \), it follows that \( E_j = 0 \), \( \forall j \geq 2 \). Let \( a_1 = 1 \) and \( a_j = \frac{\mu}{A_j} \sum_{i'=1}^{j-1} L_{i'} \). Finally, as \( A_1 = 1 \) and \( A_j = \frac{\mu}{A_j} \sum_{i'=1}^{j-1} L_{i'} \), \( \mathbb{E}[f(x_{k+1})] - f(x_*) \leq \mathbb{E}[G_k] \leq \frac{\sum_{j=1}^{k} E_j}{A_k} \). As \( A_1 = A_2 = \frac{A_2}{A_1} = \frac{A_3}{A_2} = \ldots = \frac{A_k}{A_{k-1}} \), and \( A_j = 1 - \frac{\mu}{A_j} \sum_{i'=1}^{j-1} L_{i'} \), it remains to observe that, from Proposition 3.2, \( \mathbb{E}[G_1] \leq \left(1 - \frac{\mu}{\sum_{i'=1}^{n} L_{i'}} \right)^k \cdot \frac{\left(\sum_{i'=1}^{n} L_{i'}\right) \| (f_N - f_N^k)(x_* - x_1) \|^2}{2} \).

We note that when \( n = 2 \), the asymptotic convergence of AR-BCD coincides with the convergence of alternating minimization (Beck, 2015). When \( n \)th block is empty (i.e., when all blocks are sampled with non-zero probability and there is no exact minimization over a least-smooth block), we obtain the convergence bound of the standard randomized coordinate descent method (Nesterov, 2012).

### 4. Accelerated AR-BCD

In this section, we show how to accelerate (AR-BCD) when \( f(\cdot) \) is smooth. We believe it is possible to obtain similar results in the smooth and strongly convex case, which we defer to a future version of the paper. Denote:
\[
\Delta_k = I_N^k \nabla f(x_k)/p_{ik},
\]
\[
v_k = \arg \min_{u} \left\{ \sum_{j=1}^{k} a_j \langle \Delta_j, u \rangle + \sum_{i=1}^{n} \sigma_i \| u - x_i \|^2 \right\}, \quad (4.1)
\]
where \( \sigma_i > 0 \), \( \forall i \), will be specified later. Accelerated AR-BCD (AAR-BCD) is defined as follows:

Select \( i_k \) from \( \{1, \ldots, n - 1\} \) w.p. \( p_{i_k} \),
\[
\bar{x}_{k} = \frac{A_{k-1}}{A_k} x_{k-1} + \frac{a_k}{A_k} v_{k-1},
\]
\[
x_k = \arg \min_{x \in S_n(x_k)} f(x), \quad (AAR-BCD)
\]
\[
y_k = x_k + \frac{a_k}{p_{i_k} A_k} I_N^k (v_k - v_{k-1}),
\]
where \( \sum_{i=1}^{n-1} p_i = 1 \), \( p_i > 0 \), \( \forall i \in \{1, \ldots, n - 1\} \), and \( v_k \) is defined by (4.1). To seed the algorithm, we further assume that \( y_1 = x_1 + I_N^k \frac{1}{p_{i_1}} (v_1 - x_1) \).

**Remark 4.1.** Iteration complexity of (AAR-BCD) is dominated by the computation of \( \bar{x}_k \), which requires updating an entire vector. This type of an update is not unusual for accelerated block coordinate descent methods, and in fact appears in all such methods we are aware of (Nesterov, 2012; Lee & Sidford, 2013; Lin et al., 2014; Fercq & Richtárik, 2015; Allen-Zhu et al., 2016). In most cases of practical interest, however, it is possible to implement this step efficiently (using that \( v_k \) changes only over block \( k \) in iteration \( k \)). More details are provided in Appendix B.

To analyze the convergence of AAR-BCD, we will need to construct a more sophisticated duality gap than in the previous section, as follows.

#### 4.1. Approximate Duality Gap

We define the upper bound to be \( U_k = f(y_k) \). The constructed lower bound \( L_k \) from previous subsection is not directly useful for the analysis of (AAR-BCD). Instead, we
will construct a random variable $\Lambda_k$, which in expectation is upper bounded by $f(x^*)$. The general idea, as in previous subsection, is to show that some notion of approximate duality gap decreases in expectation.

Towards constructing $\Lambda_k$, we first prove the following technical proposition, whose proof is in Appendix A.

**Proposition 4.2.** Let $x_k$ be as in (AAR-BCD). Then:

$$\mathbb{E}\left[\sum_{j=1}^{k} a_j \langle \Delta_j, x_* - x_j \rangle \right] = \mathbb{E}\left[\sum_{j=1}^{k} a_j \langle \nabla f(x_j), x_* - x_j \rangle \right].$$

Define the randomized lower bound as in Eq. (4.2), and observe that (4.1) defines $v_k$ as the argument of the minimum from $\Lambda_k$. The crucial property of $\Lambda_k$ is that it lower bounds $f(x_*)$ in expectation, as shown in the following lemma.

**Lemma 4.3.** Let $x_k$ be as in (AAR-BCD). Then $f(x_*) \geq \mathbb{E}[\Lambda_k]$.

**Proof.** By convexity of $f(\cdot)$, for any sequence $\{\tilde{x}_j\}$ from $\mathbb{R}^n$,

$$f(x_*) \geq \mathbb{E}\left[\sum_{j=1}^{k} a_j \langle f(x_j) + \langle \nabla f(x_j), x_* - x_j \rangle \rangle \right].$$

By linearity of expectation and Proposition 4.2:

$$f(x_*) \geq \mathbb{E}\left[\sum_{j=1}^{k} a_j \langle f(x_j) + \langle \Delta_j, x_* - x_j \rangle \rangle \right].$$

Adding and subtracting (deterministic) $\sum_{i=1}^{n-1} \frac{\sigma_i^2}{2} ||x_i^* - x_i^t||^2$ to/from (4.3) and using that:

$$k \sum_{j=1}^{k} a_j \langle \Delta_j, x_* - x_j \rangle + \sum_{i=1}^{n-1} \frac{\sigma_i^2}{2} ||x_i^* - x_i^t||^2$$

$$\geq \min_u \left\{ k \sum_{j=1}^{k} a_j \langle \Delta_j, u - x_j \rangle + \sum_{i=1}^{n-1} \frac{\sigma_i^2}{2} ||u_i - x_i||^2 \right\}$$

$$= \min_u m_k(u),$$

where

$$m_k(u) = \sum_{j=1}^{k} a_j \langle \Delta_j, u - x_j \rangle + \sum_{i=1}^{n-1} \frac{\sigma_i^2}{2} ||u_i - x_i||^2,$$

it follows that:

$$f(x_*) \geq \mathbb{E}\left[\sum_{j=1}^{k} a_j f(x_j) - \sum_{i=1}^{n-1} \frac{\sigma_i^2}{2} ||x_i^* - x_i^t||^2 \right]$$

$$+ \frac{\min_u m_k(u)}{A_k},$$

which is equal to $\mathbb{E}[\Lambda_k]$, and completes the proof. \qed

Similar as before, define the approximate gap as $\Gamma_k = U_k - \Lambda_k$. Then, we can bound the initial gap as follows.

**Proposition 4.4.** If $a_1 = \frac{\sigma_1^2}{2} \leq \frac{\sigma_i^2}{2}$, $\forall i \in \{1, \ldots, n-1\}$, then

$$\mathbb{E}[A_1 \Gamma_1] \leq \sum_{i=1}^{n-1} \frac{\sigma_i^2}{2} ||x_i - x_1||^2.$$

**Proof.** As $a_1 = A_1$ and $y_1$ differs from $x_1$ only over block $i = i_1$, by smoothness of $f(\cdot)$:

$$A_1 U_1 = A_1 f(y_1) \leq a_1 \langle x_1, y_1 - x_1 \rangle + \frac{a_1 L_i}{2} ||y_i^1 - x_i^1||^2.$$

On the other hand, the initial lower bound is:

$$A_1 \Lambda_1 = a_1 (f(x_1) + \langle \Delta_1, v_1 - x_1 \rangle)$$

$$+ \sum_{i=1}^{n-1} \frac{\sigma_i^2}{2} ||y_i^1 - x_i^1||^2.$$

Recall that $y_i^1 = x_i^1 + \frac{1}{L_i} (v_i^1 \cdot x_i^1)$. Using $A_1 \Gamma_1 = A_1 U_1 - A_1 \Lambda_1$ and the bounds on $U_1$, $\Lambda_1$ from the above: $A_1 \Gamma_1 \leq \sum_{i=1}^{n-1} \frac{\sigma_i^2}{2} ||x_i^* - x_i^t||^2$, as $a_1 \leq p_i \frac{\sigma_i^2}{2}$, and, thus, $\mathbb{E}[A_1 \Gamma_1] \leq \sum_{i=1}^{n-1} \frac{\sigma_i^2}{2} ||x_i^* - x_i^t||^2$.

The next part of the proof is to show that $A_k \Gamma_k$ is a supermartingale. The proof is provided in Appendix A.

**Lemma 4.5.** If $\frac{a_1^2}{A_k} \leq \frac{\sigma_1^2}{2} \frac{\sigma_i^2}{2}$, $\forall i \in \{1, \ldots, n-1\}$, then

$$\mathbb{E}[A_k \Gamma_k | F_{k-1}] \leq A_{k-1} \Gamma_{k-1}.$$

Finally, we bound the convergence of (AAR-BCD).

**Theorem 4.6.** Let $x_k, y_k$ evolve according to (AAR-BCD), for $\frac{a_1^2}{A_k} = \min_{1 \leq i \leq n-1} \frac{\sigma_i^2}{L_i}$, then:

$$\mathbb{E}[f(y_k)] - f(x_*) \leq \frac{\sum_{i=1}^{n-1} \sigma_i ||x_i^* - x_i^t||^2}{2 A_k}. \quad (4.2)$$

In particular, if $p_i = \frac{\sqrt{L_i}}{\sum_{i=1}^{n} \sqrt{L_i}}$, $\sigma_i = (\sum_{i=1}^{n-1} \sqrt{L_i})^2$,

and $a_1 = 1$, then:

$$\mathbb{E}[f(y_k)] - f(x_*) \leq \frac{2 \sum_{i=1}^{n-1} \sqrt{L_i}^2 \sum_{i=1}^{n-1} ||x_i^t - x||^2}{k(k+3)}.$$

Alternatively, if $p_i = \frac{1}{n-1}$, $\sigma_i = L_i$, and $a_1 = \frac{1}{(n-1)^2}$:

$$\mathbb{E}[f(y_k)] - f(x_*) \leq \frac{2 (n-1)^2 \sum_{i=1}^{n-1} L_i ||x_i^t - x_i^t||^2}{k(k+3)}.$$
The first part of the proof follows immediately by applying Proposition 4.4 and Lemma 4.5. The second part follows by plugging in the particular choice of parameters and observing that \( a_j \) grows faster than \( \sqrt{\frac{j+1}{2}} \) in the former, and faster than \( \frac{j+1}{2(n-1)^2} \) in the latter case.

Finally, we make a few remarks regarding Theorem 4.6. In the setting without a non-smooth block (when \( n \)th block is empty), \( \text{(AAR-BCD)} \) with sampling probabilities \( p_i \sim \sqrt{T_i} \) has the same convergence bound as the NU_ACDM algorithm (Allen-Zhu et al., 2016) and the ALPHA algorithm for smooth minimization (Qu & Richtárik, 2016). Further, when the sampling probabilities are uniform, \( \text{(AAR-BCD)} \) converges at the same rate as the ACDM algorithm (Nesterov, 2012) and the APCG algorithm applied to non-composite functions (Lin et al., 2014).

5. Numerical Experiments

To illustrate the results, we solve the least squares problem on the BlogFeedback Data Set (Buza, 2014) obtained from UCI Machine Learning Repository (Lichman, 2013). The data set contains 280 attributes and 52,396 data points. The attributes correspond to various metrics of crawled blog posts. The data is labeled, and the labels correspond to the number of comments that were posted within 24 hours from a fixed baseline. The goal of a regression method is to predict the number of comments that a blog post receives.

What makes linear regression with least squares on this dataset particularly suitable to our setting is that the smoothness parameters of individual coordinates in the least squares problem take values from a large interval, even when the data matrix \( A \) is scaled by its maximum absolute value (the values are between 0 and \( \sim 354 \)).

In all the comparisons between the different methods, we define an epoch to be equal to \( n \) iterations (this would correspond to a single iteration of a full-gradient method). The graphs plot the optimality gap of the methods over epochs, where the optimal objective value \( f^* \) is estimated via a higher precision method and denoted by \( f^\circ \). All the results are shown for 50 method repetitions, with bold lines representing the minimum\(^3 \) optimality gap over those 50 runs. The norm used in all the experiments is \( \ell_2 \), i.e., \( \| \cdot \| = \| \cdot \|_2 \).

Non-accelerated methods We first compare AR-BCD with a gradient step to RCDM (Nesterov, 2012) and standard cyclic BCD – C-BCD (see, e.g., (Beck & Tetruashvili, 2013)). To make the comparison fair, as AR-BCD makes two steps per iteration, we slow it down by a factor of two compared to the other methods (i.e., we count one iteration of AR-BCD as two). In the comparison, we consider two cases for RCDM and C-BCD: (i) the case in which these two algorithms perform gradient steps on the first \( n-1 \) blocks and exact minimization on the \( n \)th block (denoted by RCDM and C-BCD in the figure), and (ii) the case in which the algorithms perform gradient steps on all blocks (denoted by RCDM-G and C-BCD-G in the figure). The sampling probabilities for RCDM and AR-BCD are proportional to the block smoothness parameters. The permutation for C-BCD is random, but fixed in each method run.

Fig. 1(e)-1(h) shows the comparison of the described non-accelerated algorithms, for block sizes \( N/n \in \{5, 10, 20, 40\} \). The first observation to make is that adding exact minimization over the least smooth block speeds up the convergence of both C-BCD and RCDM, suggesting that the existing analysis of these two methods is not tight. Second, AR-BCD generally converges to a lower optimality gap. While RCDM makes a large initial progress, it stagnates afterwards due to the highly non-uniform sampling probabilities, whereas AR-BCD keeps making progress.

Accelerated methods Finally, we compare AAR-BCD to NU_ACDM (Allen-Zhu et al., 2016), APCG (Lin et al., 2014), and accelerated C-BCD (ABCGD) from (Beck & Tetruashvili, 2013). As AAR-BCD makes three steps per iteration (as opposed to two steps normally taken by other methods), we slow it down by a factor 1.5 (i.e., we count one iteration of AAR-BCD as 1.5). We chose the sampling probabilities of NU_ACDM and AAR-BCD to be proportional to \( \sqrt{T_i} \), while the sampling probabilities for APCG are uniform\(^4 \). Similar as before, each full run of ABCGD is performed on a random but fixed permutation of the blocks.

\(^3\) We choose to show the median as opposed to the mean, as it is well-known that in the presence of outliers the median is a robust estimator of the true mean (Hampel et al., 2011).

\(^4\) The theoretical results for APCG were only presented for uniform sampling (Lin et al., 2014).
The results are shown in Fig. 1(i)-(l). Compared to APCG (and ABCGD), NU_ACDCM and AAR-BCD converge much faster, which is expected, as the distribution of the smoothness parameters is highly non-uniform and the methods with non-uniform sampling are theoretically faster by factor of the order $\sqrt{n}$ (Allen-Zhu et al., 2016). As the block size is increased (going left to right), the discrepancy between the smoothness parameters of the least smooth block and the remaining blocks increases, and, as expected, AAR-BCD exhibits more dramatic improvements compared to the other methods.

6. Conclusion

We presented a novel block coordinate descent algorithm AR-BCD and its accelerated version for smooth minimization AAR-BCD. Our work answers the open question of (Beck & Tetruashvili, 2013) whether the convergence of block coordinate descent methods intrinsically depends on the largest smoothness parameter over all the blocks by showing that such a dependence is not necessary, as long as exact minimization over the least smooth block is possible. Before our work, such a result only existed for the setting of two blocks, using the alternating minimization method.

There are several research directions that merit further investigation. For example, we observed empirically that exact optimization over the non-smooth block improves the performance of RCDM and C-BCD, which is not justified by the existing analytical bounds. We expect that in both of these methods the dependence on the least smooth block can be removed, possibly at the cost of a worse dependence on the number of blocks. Further, AR-BCD and AAR-BCD are mainly useful when the discrepancy between the largest block smoothness parameter and the remaining smoothness parameters is large, while under uniform distribution of the smoothness parameters it can be slower than other methods by a factor 1.5-2. It is an interesting question whether there are modifications to AR-BCD and AAR-BCD that would make them uniformly better than the alternatives.
