Deep Models of Interactions Across Sets

Jason Hartford * 1  Devon R Graham * 1  Kevin Leyton-Brown 1  Siamak Ravanbakhsh 1

Abstract

We use deep learning to model interactions across two or more sets of objects, such as user–movie ratings, protein–drug bindings, or ternary user–item–tag interactions. The canonical representation of such interactions is a matrix (or a higher-dimensional tensor) with an exchangeability property: the encoding’s meaning is not changed by permuting rows or columns. We argue that models should hence be Permutation Equi-variant (PE): constrained to make the same predictions across such permutations. We present a parameter-sharing scheme and prove that it could not be made any more expressive without violating PE. This scheme yields three benefits. First, we demonstrate state-of-the-art performance on multiple matrix completion benchmarks. Second, our models require a number of parameters independent of the numbers of objects, and thus scale well to large datasets. Third, models can be queried about new objects that were not available at training time, but for which interactions have since been observed. In experiments, our models achieved surprisingly good generalization performance on this matrix extrapolation task, both within domains (e.g., new users and new movies drawn from the same distribution used for training) and even across domains (e.g., predicting music ratings after training on movies).

1. Introduction

Suppose we are given a set of users \( \mathbb{N} = \{1, \ldots, N\} \), a set of movies \( \mathbb{M} = \{1, \ldots, M\} \), and their interaction in the form of tuples \( \mathbb{X} = \{(n, m, x)\} \) with \( n \in \mathbb{N}, m \in \mathbb{M} \) and \( x \in \mathbb{R} \). The canonical representation of such a function is a matrix \( X \in \mathbb{R}^{N \times M} \); of course, we want \( X_{n,m} = x \) for each \( (n, m, x) \in \mathbb{X} \). Learning our function corresponds to matrix completion: using patterns in \( \mathbb{X} \) to predict values for the remaining elements of \( X \). \( X \) is what we will call an exchangeable matrix: any row- and column-wise permutation of \( X \) represents the same set of ratings and hence the same matrix completion problem.

Exchangeability has a long history in machine learning and statistics. de Finetti’s theorem states that exchangeable sequences are the product of a latent variable model. Extensions of this theorem characterize distributions over other exchangeable structures, from matrices to graphs; see Orbânz & Roy (2015) for a detailed treatment. In machine learning, a variety of frameworks formalize exchangeability in data, from plate notation to statistical relational models (Raedt et al., 2016; Getoor & Taskar, 2007). When dealing with exchangeable arrays (or tensors), a common approach is tensor factorization. In particular, one thread of work leverages tensor decomposition for inference in latent variable models (Anandkumar et al., 2014). However, in addition to having limited expressive power, tensor factorization requires retraining models for each new input.

We call a learning algorithm Permutation Equivariant (PE) if it is constrained to give the same answer across all exchangeable inputs; we argue that PE is an important form of inductive bias in exchangeable domains. However, it is not trivial to achieve; indeed, all existing parametric factorization and matrix/tensor completion methods associate parameters with each row and column, and thus are not PE. How can we enforce this property? One approach is to augment the input with all \( M! \times N! \) permutations of rows and columns. However, this is computationally wasteful and becomes infeasible for all but the smallest \( N \) and \( M \). Instead, we show that a simple parameter-sharing scheme suffices to ensure that a deep model can represent only PE functions. The result is analogous to the idea of a convolution layer: a lower-dimensional effective parameter space that enforces a desired equivariance property. Indeed, parameter-sharing is a generic and efficient approach for achieving equivariance in deep models (Ravanbakhsh et al., 2017).

When the matrix models the interaction between the members of the same group, one could further con-
strain permutations to be identical across both rows and columns. An example of such a jointly exchangeable matrix (Orbanz & Roy, 2015), modelling the interaction of the nodes in a graph, is the adjacency matrix deployed by graph convolution. Our approach reduces to graph convolution in the special case of 2D arrays with this additional parameter-sharing constraint, but also applies to arbitrary matrices and higher dimensional arrays.

Finally, we explain connections to some of our own past work. First, we introduced a similar parameter-sharing scheme in the context of behavioral game theory (Hartford et al., 2016): rows and columns represented players’ actions and the exchangeable matrix encoded payoffs. The current work provides a theoretical foundation for these ideas and shows how a similar architecture can be applied much more generally. Second, our model for exchangeable matrices can be seen as a generalization of the deep sets architecture (Zaheer et al., 2017), where a set can be seen as a one-dimensional exchangeable array.

In what follows, we begin by introducing our parameter-sharing approach in Section 2, considering the cases of both dense and sparse matrices. In Section 3.2 we study two architectures for matrix completion that use an exchangeable matrix layer. In particular the factorized autoencoding model provides a powerful alternative to commonly used matrix factorization methods; notably, it does not require retraining to be evaluated on previously unseen data. In Section 4 we present extensive results on benchmark matrix completion datasets. We generalize our approach to higher-dimensional tensors in Section 5.

2. Exchangeable Matrix Layer

Let $X \in \mathbb{R}^{N \times M}$ be our “exchangeable” input matrix. We use $\text{vec}(X) \in \mathbb{R}^{NM}$ to denote its vectorized form and $\text{vec}^{-1}(x)$ to denote the inverse of the vectorization that reshapes a vector of length $NM$ into an $N \times M$ matrix—i.e., $\text{vec}^{-1}(\text{vec}(X)) = X$. Consider a fully connected layer $Y := \text{vec}^{-1}(\sigma(W \text{vec}(X)))$ where $\sigma$ is an element-wise nonlinear function such as sigmoid, $W \in \mathbb{R}^{NM \times NM}$, and $Y \in \mathbb{R}^{N \times M}$ is the output matrix. Exchangeability of $X$ motivates the following property: suppose we permute the rows and columns $X$ using two arbitrary permutation matrices $G(N) \in \{0, 1\}^{N \times N}$ and $G(M) \in \{0, 1\}^{M \times M}$ to get $X' := G(N)XG(M)$. Permutation Equivariance (PE) requires the new output matrix $Y' := \text{vec}^{-1}(\sigma(W \text{vec}(X'))) \equiv \text{vec}^{-1}(\sigma(W \text{vec}(X)))G(M)$ to experience the same permutation of rows and columns—that is, we require $Y' = G(N)YG(M)$.

**Definition 2.1 (exchangeable matrix layer, simplified)**

Given $X \in \mathbb{R}^{N \times M}$, a fully connected layer $\sigma(W \text{vec}(X))$ with $W \in \mathbb{R}^{NM \times NM}$ is called an exchangeable matrix layer if, for all permutation matrices $G(N) \in \{0, 1\}^{N \times N}$ and $G(M) \in \{0, 1\}^{M \times M}$, permutation of the rows and columns results in the same permutations of the output:

$$\text{vec}^{-1}(\sigma(W \text{vec}(G(N)XG(M)))) = G(N) \text{vec}^{-1}(\sigma(W \text{vec}(X)))G(M).$$

This requirement heavily constrains the weight matrix $W$; indeed, its number of effective degrees of freedom cannot even grow with $N$ and $M$. Instead, the resulting layer is forced to have the following, simple form:

$$W_{(n,m),(n',m')} := \begin{cases} w_1 & n = n', m = m' \\ w_2 & n = n', m \neq m' \\ w_3 & n \neq n', m = m' \\ w_4 & n \neq n', m \neq m'. \end{cases}$$

For each output element $Y_{n,m}$, we have the following parameters: one connecting it to its counterpart $X_{n,m}$, one

---

1This definition is simplified to ease exposition; the full definition (see Section 5) adds the additional constraint that the layer not be equivariant wrt any other permutation of the elements of $X$. Otherwise, a trivial layer with a constant weight matrix $W_{n,m} = c$ would also satisfy the stated equivariance property.
This parameter sharing is translated to summing or averaging elements across rows and columns; more generally, PE is preserved by any commutative pooling operation. Moreover, stacking multiple layers with the same equivariance properties preserves equivariance (Ravanbakhsh et al., 2017). This allows us to build deep PE models.

**Multiple Input–Output Channels** Equation (3) describes the layer as though it has single input and output matrices. However, as with convolution, we may have $K$ input and $O$ output channels. We use superscripts $X^{(k)}$ and $Y^{(o)}$ to denote such channels. Cross-channel interactions are fully connected—that is, we have five unique parameters $w_1^{(k,o)}, \ldots, w_5^{(k,o)}$ for each combination of input–output channels; note that the bias parameter $w_0$ does not depend on the input. Similar to convolution, the number of channels provides a tuning nob for the expressive power of the model. In this setting, the scalar output $Y_{n,m}$ is given as

$$Y_{n,m}^{(o)} = \sigma \left( \sum_{k=1}^{K} \left( w_1^{(k,o)} X_{n,m}^{(k)} + \frac{w_2^{(k,o)}}{N} \sum_{n'} X_{n',m}^{(k)} + \frac{w_3^{(k,o)}}{M} \sum_{m'} X_{n,m'}^{(k)} + \frac{w_4^{(k,o)}}{N M} \sum_{n'} X_{n,m'}^{(k)} + w_5^{(o)} \right) \right)$$

**Input Features for Rows and Columns** In some applications, in addition to the matrix $X \in \mathbb{R}^{N \times M \times K}$, where $K$ is the number of input channels/features, we may have additional features for rows $R \in \mathbb{R}^{N \times K'}$ and/or columns $C \in \mathbb{R}^{M \times K''}$. We can preserve PE by broadcasting these row/column features over the whole matrix and treating them as additional input channels.

**Jointly Exchangeable Matrices** For jointly exchangeable matrices, such as adjacency matrix, Equation (1) is constrained to have $N = M$ and $G^{(N)} = G^{(M)}$. This will in turn constrain the corresponding parameter-sharing so that $w_2 = w_3$ in Equation (2).

**2.1. Sparse Inputs**

Real-world arrays are often extremely sparse. Indeed, matrix and tensor completion is only meaningful with missing entries. Fortunately, the equivariance properties of Theorem 2.1 continue to hold when we only consider the nonzero (observed) entries. For sparse matrices, we continue to use the same parameter-sharing scheme across rows and columns, with the only difference being that we limit the model to observed entries. We now make this precise.

Let $X \in \mathbb{R}^{N \times M \times K}$ be a sparse exchangeable array with $K$ channels, where all the channels for each row-column pair $(n,m)$ are either fully observed or completely missing. Let $I$ identify the set of such non-zero indices. Let $R_n = \{m | (n,m) \in I\}$ be the non-zero entries in the $n^{th}$ row of $X$, and let $C_m$ be the non-zero entries of its $m^{th}$ column. This sparse matrix, the terms in the layer of (4) are adapted as one would expect:

$$\frac{w_2^{(k,o)}}{N} \sum_{n'} X_{n',m}^{(k)} \rightarrow \frac{w_2^{(k,o)}}{|I|} \sum_{n' \in I} X_{n',m}^{(k)}$$

$$\frac{w_3^{(k,o)}}{M} \sum_{m'} X_{n,m'}^{(k)} \rightarrow \frac{w_3^{(k,o)}}{|R_n|} \sum_{m \in R_n} X_{n,m}^{(k)}$$

$$\frac{w_4^{(k,o)}}{N M} \sum_{n'} X_{n',m'}^{(k)} \rightarrow \frac{w_4^{(k,o)}}{|I|} \sum_{(n',m') \in I} X_{n',m'}^{(k)}$$

**3. Matrix Factorization and Completion**

Recommender systems are very widely applied, with many modern applications suggesting new items (e.g., movies, friends, restaurants, etc.) to users based on previous ratings of other items. The core underlying problem is naturally posed as a matrix completion task: each row corresponds to a user and each column corresponds to an item; the matrix has a value for each rating given to an item by a given user; the goal is to fill in the missing values of this matrix.

In Section 3.1 we review two types of analysis in dealing with exchangeable matrices. Section 3.2 introduces two architectures: a self-supervised model—a simple composition of exchangeable matrix layers—that is trained to produce randomly removed entries of the observed matrix during the training; and a factorized model that uses an auto-encoding nonlinear factorization scheme. While there are innumerable methods for (nonlinear) matrix factorization and completion, both of these models are the first to generalize to inductive settings while achieving competitive performance.
in transductive settings. Section 3.3 introduces two subsampling techniques for large sparse matrices followed by a literature review in Section 3.4.

### 3.1. Inductive and Transductive Analysis

In matrix completion, during training we are given a sparse input matrix $X_{ts}$ with observed entries $I_{ts} = \{(n, m)\}$. At test time, we are given $X_{ts}$ with observed entries $I_{ss} = \{(n', m')\}$, and we are interested in predicting (some of) the missing entries of $X_{ts}$, expressed through $I'_{ts}$. In the transductive or matrix interpolation setting, $I_{ts}$ and $I_{ss}$ have overlapping rows and/or columns—that is, at least one of the following is true: $\{(m, (n, m)) \in I\} \cap \{(m', (n', m')) \in I'\} \neq \emptyset$ or $\{n, (n, m) \in I\} \cap \{(n', (n', m')) \in I'\} \neq \emptyset$. In fact, often $X_{ts}$ and $X_{ss}$ are identical. Conversely, in the inductive or matrix extrapolation setting, we are interested in making predictions about completely unseen entries: the training and test row/column indices are completely disjoint. We will even consider cases where $X_{ts}$ and $X_{ss}$ are completely different datasets—e.g., movie-rating vs music-rating. The same distinction applies in matrix factorization. Training a model to factorize a particular given matrix is transductive, while factorizing unseen matrices after training is inductive.

### 3.2. Architectures

#### Self-supervised Exchangeable Model

When the task is matrix completion, a simple deep yet PE model is a composition of exchangeable matrix layers. That is the function $f_{ss} : \mathbb{R}^{N \times M \times K} \rightarrow \mathbb{R}^{N \times M \times K}$ is simply a composition of exchangeable matrix layers. Given the matrix $X$ with observed entries $I$, we divide $I = I_{ts} \cup I_{pr}$ into disjoint input and prediction entries. We then train $f_{ss}(X_{ts})$ to predict the prediction entries $X_{pr}$.

#### Factorized Exchangeable Autoencoder (FEA)

Our factorized autoencoder is composed of an encoder and a decoder. The encoder $f_{enc} : \mathbb{R}^{N \times M \times K} \rightarrow \mathbb{R}^{K_N \times N \times K_M \times M}$ maps the (sparse) input matrix $X \in \mathbb{R}^{N \times M \times K}$ to a row-factor $Z_N \in \mathbb{R}^{K_N \times N}$ and a column-factor $Z_M \in \mathbb{R}^{K_M \times M}$. To do so, the encoder uses a composition of exchangeable matrix layers. The output of the final layer $Y^l \in \mathbb{R}^{N \times M \times K^l}$ is pooled across rows and columns (and optionally passed through a feed-forward layer) to produce latent factors $Z_N$ and $Z_M$. The decoder $g_{dec} : \mathbb{R}^{K_N \times N \times M \times M} \rightarrow \mathbb{R}^{N \times M \times K}$ also uses a composition of exchangeable matrix layers, and reconstructs the input matrix $X$ from the factors. The optimization objective is to minimize reconstruction error $\ell(X, g_{dec}(f_{enc}(X)))$; similar to classical auto-encoders.

This procedure is also analogous to classical matrix factorization, with an important distinction that once trained, we can readily factorize the unseen matrices without performing any optimization. Note that the same architecture trivially extends to tensor-factorization, where we use an exchangeable tensor layer (see Section 5).

#### Channel Dropout

Both the factorized autoencoder and self-supervised exchangeable model are flexible enough to make regularization important for good generalization performance. Dropout (Srivastava et al., 2014) can be extended to apply to exchangeable matrix layers by noticing that each channel in an exchangeable matrix layer is analogous to a single unit in a standard feed-forward network. We therefore randomly drop out whole channels during training (as opposed to dropping out individual elements). This procedure is equivalent to the SpatialDropout technique used in convolutional networks (Tompson et al., 2015).

### 3.3. Subsampling in Large Matrices

A key practical challenge arising from our approach is that our models are designed to take the whole data matrix $X$ as input and will make different (and typically worse) predictions if given only a subset of the data matrix. As datasets grow, the model and input data become too large to fit within fixed-size GPU memory. This is problematic both during training and at evaluation time because our models rely on aggregating shared representations across data points to make their predictions. To address this, we explore two subsampling procedures.

#### Uniform sampling

The simplest approach is to sample sub-matrices of $X$ by uniformly sampling from its (typically sparse) elements. This has the advantage that each submatrix is an unbiased sample of the full matrix and that the procedure is computationally cheap, but has the potential to limit the performance of the model because the relationships between the elements of $X$ are sparsified.

#### Conditional sampling

Rather than sparsifying interactions between all set members, we can pick a subset of rows and columns and maintain all their interactions; see Figure 4. This procedure is unbiased as long as each element $(n, m) \in I$ has the same probability of being sampled. To achieve this, we first sample a subset of rows $N' \subseteq N = \{1, \ldots, N\}$ from the marginal $P(n) := \frac{[n]}{\|N\|}$, followed by subsampling of columns using the marginal...
distribution over the columns, within the selected rows: 
\[ P(m | \mathbb{N}') = \frac{\{(m',n) \in \mathbb{M}' | (m',n) \in \mathbb{N}'\}}{\{(m',n) \in \mathbb{M}' | (m',n) \in \mathbb{N}'\}}. \]
This gives us a set of columns \( \mathbb{M}' \subseteq \mathbb{M} \). We consider any observation within \( \mathbb{N}' \times \mathbb{M}' \) as our subsample: 
\[ \mathbb{I}_{\text{sample}} := \{(n,m) \in \mathbb{I} | n \in \mathbb{N}', m \in \mathbb{M}'\}. \]
This sampling procedure is more expensive than uniform sampling, as we have to calculate conditional marginal distributions for each set of samples.

![Uniform sampling](image1.png) ![Conditional sampling](image2.png)

**Figure 4.** Uniform sampling (left) selects samples (red) uniformly from the non-zero indices of the matrix \( \mathbb{X} \) while conditional sampling (right) first samples a set of rows (shown in orange) from the row marginal distribution (green) and then selects sample from the resulting column conditional distribution.

**Sampling at test time**  At training time all we must ensure is that we sample in an unbiased way; however, at test time we need to ensure that the test indices \( \mathbb{I}_t \) of large test matrix \( \mathbb{X}_t \) are all sampled. Fortunately, according to the *coupon collectors’ lemma*, in expectation we only need to repeat random sampling of indices \( \log(|\mathbb{I}_t|) \) times more (\( \approx 10\times \) in practice) than an ideal partitioning of \( \mathbb{I}_t \), in order to cover all the relevant indices.

### 3.4. Related Literature

The literature in matrix factorization and completion is vast. The classical approach to solving the matrix completion problem is to find some low rank (or sparse) approximation that minimizes a reconstruction loss for the observed ratings (see e.g., Candès & Recht, 2009; Koren et al., 2009; Mnih & Salakhutdinov, 2008). Because these procedures learn embeddings for each user and item to make predictions, they are transductive, meaning they can only make predictions about users and items observed during training. To our knowledge this is also true for all recent deep factorization and other collaborative filtering techniques (e.g., Salakhutdinov et al., 2007; Deng et al.; Sedhain et al., 2015; Wang et al., 2015; Li et al., 2015; Zheng et al., 2016; Dziugaite & Roy, 2015). An exception is a recent work by Yang et al. (2016) that extends factorization-style approaches to the inductive setting (where predictions can be made on unseen users and items). However their method relies on additional side information to represent users and items. By contrast, our approach is able to make inductive completions on rating matrices that may differ from that which was observed during training without using any side information (though our approach can easily incorporate side information).

Matrix completion may also be posed as predicting edge weights in bipartite graphs (Berg et al., 2017; Monti et al., 2017). This approach builds on recent work applying convolutional neural networks to graph-structured data (Scarselli et al., 2009; Bruna et al., 2014; Duvenaud et al., 2015; Defferrard et al., 2016; Kipf & Welling, 2016; Hamilton et al., 2017). As we saw, parameter sharing in graph convolution is closely related to parameter sharing in exchangeable matrices, and indeed it is a special case where \( w_2 = w_3 \) in Equation (2).

### 4. Empirical Results

For reproducibility we have released Tensorflow and Pytorch implementations of our model. Details on the training and architectures appear in the appendix. Section 4.1 reports experimental results in the standard transductive (matrix interpolation) setting. However, more interesting results are reported in Section 4.2, where we test a trained deep model on a completely different dataset. Finally Section 4.3 compares the model’s performance when using different sampling procedures. The datasets used in our experiments are summarized in Table 1.

MovieLens data sets are standard (Harper & Konstan, 2015), as is Netflix, while for Flixster, Douban and Yahoo Music we used the \( 3000 \times 3000 \) submatrix presented by (Monti et al., 2017) for comparison purposes.

#### 4.1. Transductive Setting (Matrix Interpolation)

Here, we demonstrate that exploiting the PE structure of the exchangeable matrices allows us to achieve results competitive with state-of-the-art, while maintaining a constant number of parameters. Note that the number of parameters in all the competing methods grow with \( N \) and/or \( M \).

In Table 2 we report that the self-supervised exchangeable model is able to achieve state of the art performance on

MovieLens-100K dataset. For MovieLens-1M dataset, we cannot fit the whole dataset into the GPU memory for training and therefore use conditional subsampling; also see Section 4.3. Our results on this dataset are summarized in Table 3. On this larger dataset both models gave comparatively weaker performance than what we observed on the smaller ML-100k dataset and in the extrapolation results. We suspect this is largely due to memory constraints: there is a trade-off between the size of the model (in terms of number of layers and units per layer) and the batch size one can train. We found that both larger batches and deeper models tended to offer better performance, but on these larger datasets it is not currently possible to have both. The results for the factorized exchangeable autoencoder architecture are similar and reported in the same table.

4.2. Inductive Setting (Matrix Extrapolation)

Because our model does not rely on any per-user or per-movie parameters, it should be able to generalize to new users and movies that were not present during training. We tested this by training an exchangeable factorized autoencoder on the MovieLens-100k dataset and then evaluating it on a subsample of data from the MovieLens-1M dataset. At test time, the model was shown a portion of the new ratings and then made to predict the remaining ratings. Figure 5 summarizes the results where we vary the amount of data shown to the model from 5% of the new ratings up to 95% and compare against K-nearest neighbours approaches. Our model significantly outperforms the baselines in this task and performance degrades gracefully as we reduce the amount of data observed.

Extrapolation to new datasets Perhaps most surprisingly, we were able to achieve competitive results when training and testing on completely disjoint datasets. For this experiment we stress-tested our model’s inductive ability by testing how it generalizes to new datasets without retraining. We used a Factorized Exchangeable Autoencoder that was trained to make predictions on the MovieLens-100k dataset and tasked it with making predictions on the Flixster, Douban and YahooMusic datasets. We then evaluated its performance against models trained for each of these individual datasets. All the datasets involve rating prediction tasks, so they share some similar semantics with MovieLens, but they have different user bases and (in the case of YahooMusic) deal with music not movie ratings, so we may expect some change in the rating distributions and user-item interactions. Furthermore, the Flixster ratings are in 0.5 point increments from 1 – 5 and YahooMusic allows ratings from 1 – 100, while Douban and MovieLens ratings are on 1 – 5 scale. To account for the different rating scales, we simply binned the inputs to our model to a 1 – 5 range and, where applicable, linearly rescaled the output before comparing it to the true rating. Despite all of this, Table 4 shows that our model achieves very competitive results with models that were trained for the task.

For comparison, we also include the performance of a Factorized EAE trained on the respective datasets. This image shows that our model achieves very competitive results with models that were trained for the task.

3Because of this binning procedure, our model received input data that is considerably coarser-grained than that which was used for the comparison models.
Table 4. Evaluation of our model’s ability to generalize across datasets. We trained a factorized model on ML100k and then evaluat ed it on four new datasets. Results for the smaller datasets are taken from (Berg et al., 2017). Netflix Baseline shows state of the art prior to the Netflix Challenge.

4.3. Comparison of sampling procedures

We evaluated the effect of subsampling the input matrix $X$ on performance, for the MovieLens-100k dataset. The results are summarized in Figure 6. The two key findings are: I) even with large batch sizes of 20 000 examples, performance for both sampling methods is diminished compared to the full batch case. We suspect that our models’ weaker results on the larger ML-1M dataset may be partially attributed to the need to subsample. II) the conditional sampling method was able to recover some of the diminished performance but we leave that to future work.

5. Extention to Tensors

In this section we generalize the exchangeable matrix layer to higher-dimensional arrays (tensors) and formalize its optimal qualities. Suppose $X \in \mathbb{R}^{N_1 \times \ldots \times N_D}$ is our $D$- dimensional data tensor, and $\text{vec}(X)$ its vectorized form. We index $\text{vec}(X)$ by tuples $(n_1, n_2, \ldots, n_D)$, corresponding to the original dimensions of $X$. The precise method of vectorization is irrelevant, provided it is used consistently. Let $N = \prod_i N_i$ and let $\underline{n} = (n_i, \ldots, n_i)$ be an element of $N_1 \times \ldots \times N_D$ such that $n_i$ is the value of the $i$-th entry of $\underline{n}$, and $n_i - 1$ the values of the remaining entries (where it is understood that the ordering of the elements of $\underline{n}$ is unchanging). We seek a layer that is equivariant only to certain, meaningful, permutations of $\text{vec}(X)$. This motivates our definition of an exchangeable tensor layer in a manner that is completely analogous to Definition 2.1 for matrices.

For any positive integer $N$, let $\delta^{(N)}$ denote the symmetric group of all permutations of $N$ objects. Then $\delta^{(N_1)} \times \ldots \times \delta^{(N_D)}$ refers to the product group of all permutations of $N_1$ through $N_D$ objects, while $\delta^{(N)}$ refers to the group of all permutations of $N = \prod_i N_i$ objects. So $\delta^{(N_1)} \times \ldots \times \delta^{(N_D)}$ is a proper subgroup of $\delta^{(N)}$ having $\prod_i (N_i)!$ members, compared to $(\prod_i N_i)!$ members in $\delta^{(N)}$. We want a layer that is equivariant to only those permutations in $\delta^{(N_1)} \times \ldots \times \delta^{(N_D)}$, but not to any other member of $\delta^{(N)}$.

Definition 5.1 (exchangeable tensor layer) Let $g^{(N)} \in \delta^{(N_1)} \times \delta^{(N_2)} \times \ldots \times \delta^{(N_D)}$ and $G^{(N)}$ be the corresponding permutation matrix. Then the neural layer $\text{vec}^{-1}(\sigma(W\text{vec}(X)))$ with $X \in \mathbb{R}^{N_1 \times \ldots \times N_D}$ and $W \in \mathbb{R}^{N_1 \times \ldots \times N_D \times K}$ forms an exchangeable tensor layer.
\( \mathbb{R}^{N \times N} \) is an exchangeable tensor layer if permuting the elements of the input along any set of axes results in the same permutation of the output tensor:

\[
G^{(N)} \sigma(W \text{vec}(X)) = \sigma(W G^{(N)} \text{vec}(X)) \quad \forall X, \tag{5}
\]

and moreover for any other permutation of the elements \( X \) (i.e., permutations that are not along axes), there exists an input \( X \) for which this equality does not hold.

The following theorem asserts that a simple parameter tying scheme achieves the desired permutation equivariance for tensor-structured data.

**Theorem 5.1** The layer \( Y = \text{vec}^{-1}(\sigma(W \text{vec}(X))) \), where \( \sigma \) is any strictly monotonic, element-wise nonlinearity (e.g., sigmoid), is an exchangeable tensor layer iff the parameter matrix \( W \in \mathbb{R}^{N \times N} \) is defined as follows.

For each \( S \subseteq [D] = \{1, \ldots, D\} \), define a distinct parameter \( w_S \in \mathbb{R} \), and tie the entries of \( W \) as follows

\[
W_{\#,n'} := w_S \quad \text{s.t.} \quad n_i = n_i' \iff i \in S. \tag{6}
\]

That is, the \( (n_i, n_i') \)th element of \( W \) is uniquely determined by the set of indices at which \( n \) and \( n' \) are equal.

In the special case that \( X \in \mathbb{R}^{N_1 \times N_2} \) is a matrix, this gives the formulation of \( W \) described in Section 2. Theorem 5.1 says that a layer constructed in this manner is equivariant with respect to only those permutations of \( N \) objects that correspond to permutations of sub-tensors along the \( D \) dimensions of the input. The proof is in the Appendix. Equivariance with respect to permutations in \( S^{(N_1)} \times S^{(N_2)} \times \ldots \times S^{(N_D)} \) follows as a simple corollary of Theorem 2.1 in (Ravanbakhsh et al., 2017). Non-equivariance with respect to other permutations follows from the following Propositions.

**Proposition 5.2** Let \( g^{(N)} \in S^{(N)} \) be an “illegal” permutation of elements of the tensor \( X \) – that is \( g^{(N)} \notin S^{(N_1)} \times S^{(N_2)} \times \ldots \times S^{(N_D)} \). Then there exists a dimension \( i \in [D] \) such that, for some \( n_i, n_i', n_{-i}, n_{-i}' \):

\[
g^{(N)}((n_i, n_{-i})) = (n_i', n_{-i}) \quad \text{but} \quad g^{(N)}((n_i, n_{-i}')) \neq (n_i', n_{-i}').
\]

If we consider the sub-tensor of \( X \) obtained by fixing the value of the \( i \)th dimension to \( n_{-i} \), we expect a “legal” permutation to move this whole subtensor to some \( n'_i \) (it could additionally shuffle the elements within this subtensor.) This Proposition asserts that an “illegal” permutation \( g^{(N)} \notin S^{(N_1)} \times S^{(N_2)} \times \ldots \times S^{(N_D)} \) is guaranteed to violate this constraint for some dimension/subtensor combination. The next proposition asserts that if we can identify such inconsistency in permutation of sub-tensors then we can identify and entry in \( G^{(N)} W \) that will differ from \( W G^{(N)} \), and therefore for some input tensor \( X \), the equivariance property is violated – i.e., \( G^{(N)} \sigma(W \text{vec}(X)) \neq \sigma(W G^{(N)} \text{vec}(X)) \).

**Proposition 5.3** Let \( g^{(N)} \in S^{(N)} \) with \( G^{(N)} \in \{0,1\}^{N \times N} \) the corresponding permutation matrix. Suppose \( g^{(N)} \notin S^{(N_1)} \times S^{(N_2)} \times \ldots \times S^{(N_D)} \), and let \( W \in \mathbb{R}^{N \times N} \) be as defined above. If there exists an \( i \in [D] \), and some \( n_i, n_i', n_{-i}, n_{-i}' \) such that

\[
g^{(N)}((n_i, n_{-i})) = (n_i', n_{-i}), \quad \text{and} \quad g^{(N)}((n_i, n_{-i}')) \neq (n_i', n_{-i}'),
\]

then

\[
(G^{(N)} W)_{(n_i', n_{-i}'),(n_i, n_{-i})} \neq (W G^{(N)})_{(n_i', n_{-i}'),(n_i, n_{-i})}
\]

Proposition 5.3 makes explicit a particular element at which the products \( G^{(N)} W \) and \( W G^{(N)} \) will differ, provided \( g^{(N)} \) is not of the desired form.

Theorem 5.1 shows that this parameter sharing scheme produces a layer that is equivariant to exactly those permutations we desire, and moreover, it is optimal in the sense that any layer having fewer ties in its parameters (i.e., more parameters) would fail to be equivariant.

**Conclusion**

This paper has considered the problem of predicting relationships between the elements of two or more distinct sets of objects, where the data can also be expressed as an exchangeable matrix or tensor. We introduced a weight tying scheme enabling the application of deep models to this type of data. We proved that our scheme always produces permutation equivariant models and that no increase in model expressiveness is possible without violating this guarantee. Experimentally, we showed that our models achieve state-of-the-art or competitive performance on widely studied matrix completion benchmarks. Notably, our models achieved this performance despite having a number of parameters independent of the size of the matrix to be completed, unlike all other approaches that offer strong performance. Also unlike these other approaches, our models can achieve competitive results for the problem of matrix extrapolation: asking an already-trained model to complete a new matrix involving new objects that were unobserved at training time. Finally, we observed that our methods were surprisingly strong on various transfer learning tasks: extrapolating from MovieLens ratings to Fixter, Douban, and YahooMusic ratings. All of these contained different user populations and different distributions over the objects being rated; indeed, in the YahooMusic dataset, the underlying objects were not even of the same kind as those rated in training data.
