Differentially Private Matrix Completion Revisited

Prateek Jain 1  Om Thakkar 2  Abhradeep Thakurta 3

Abstract

We provide the first provably joint differentially private algorithm with formal utility guarantees for the problem of user-level privacy-preserving collaborative filtering. Our algorithm is based on the Frank-Wolfe method, and it consistently estimates the underlying preference matrix as long as the number of users \( m \) is \( \omega(n^{3/4}) \), where \( n \) is the number of items, and each user provides her preference for at least \( \sqrt{n} \) randomly selected items. Along the way, we provide an optimal differentially private algorithm for singular vector computation, based on the celebrated Oja’s method, that provides significant savings in terms of space and time while operating on sparse matrices. We also empirically evaluate our algorithm on a suite of datasets, and show that it consistently outperforms the state-of-the-art private algorithms.

1. Introduction

Collaborative filtering (or matrix completion) is a popular approach for modeling the recommendation system problem, where the goal is to provide personalized recommendations about certain items to a user (Koren & Bell, 2015). In other words, the objective of a personalized recommendation system is to learn the entire users-items preference matrix \( Y^* \in \mathbb{R}^{m \times n} \) using a small number of user-item preferences \( Y^*_{ij}, (i,j) \in [m] \times [n] \), where \( m \) is the number of users and \( n \) is the number of items. Naturally, in absence of any structure in \( Y^* \), the problem is ill-defined as the unknown entries of \( Y^* \) can be arbitrary. Hence, a popular modeling hypothesis is that the underlying preference matrix \( Y^* \) is low-rank, and thus, the collaborative filtering problem reduces to that of low-rank matrix completion (Recht, 2011; Candes & Recht, 2012). One can also enhance this formulation using side-information like user-features or item-features (Yu et al., 2014).

Naturally, personalization problems require collecting and analyzing sensitive customer data like their preferences for various items, which can lead to serious privacy breaches (Korolova, 2010; Narayanan & Shmatikov, 2010; Calandrino et al., 2011). In this work, we attempt to address this problem of privacy-preserving recommendations using collaborative filtering (McSherry & Mironov, 2009; Liu et al., 2015). We answer the following question in the affirmative: Can we design a matrix completion algorithm which keeps all the ratings of a user private, i.e., guarantees user-level privacy while still providing accurate recommendations? In particular, we provide the first differentially private (Dwork et al., 2006b) matrix completion algorithms with provable accuracy guarantees. Differential privacy (DP) is a rigorous privacy notion which formally protects the privacy of any user participating in a statistical computation by controlling her influence to the final output.

Most of the prior works on DP matrix completion (and low-rank approximation) (Blum et al., 2005; Chan et al., 2011; Hardt & Roth, 2012; 2013; Kapralov & Talwar, 2013; Dwork et al., 2014b) have provided guarantees which are non-trivial only in the entry-level privacy setting, i.e., they preserve privacy of only a single rating of a user. Hence, they are not suitable for preserving a user’s privacy in practical recommendation systems. In fact, their trivial extension to user-level privacy leads to vacuous bounds (see Table 1). Some works (McSherry & Mironov, 2009; Liu et al., 2015) do serve as an exception, and directly address the user-level privacy problem. However, they only show empirical evidences of their effectiveness; they do not provide formal error bounds. In contrast, we provide an efficient algorithm based on the classic Frank-Wolfe (FW) procedure (Frank & Wolfe, 1956), and show that it gives strong utility guarantees while preserving user-level privacy. Furthermore, we empirically demonstrate its effectiveness on various benchmark datasets.

Our private FW procedure needs to compute the top right singular vector of a sparse user preference matrix, while

preserving DP. For practical recommendation systems with a large number of items, this step turns out to be a significant bottleneck both in terms of space as well as time complexity. To alleviate this issue, we provide a method, based on the celebrated Oja’s algorithm (Jain et al., 2016), which is nearly optimal in terms of the accuracy of the computed singular vector while still providing significant improvement in terms of space and computation. In fact, our method can be used to speed-up even the vanilla differentially private PCA computation (Dwork et al., 2013). To the best of our knowledge, this is the first algorithm for DP singular value computation with optimal utility guarantee, that also exploits the sparsity of the underlying matrix.

Notion of privacy: To measure privacy, we select differential privacy, which is a de-facto privacy notion for large-scale learning systems, and has been widely adopted by the academic community as well as big corporations like Google (Erlingsson et al., 2014), Apple (McMillan, 2016), etc. The underlying principle of standard DP is that the output of the algorithm should not change significantly due to presence or absence of any user. In the context of matrix completion, where the goal is to release the entire preference matrix while preserving privacy, this implies that the computed ratings/preferences for any particular user cannot depend strongly on her own personal preferences. Naturally, the resulting preference computation is going to be trivial and inaccurate (which also follows from the reconstruction attacks of (Dinur & Nissim, 2003) and (Hardt & Roth, 2012)).

To alleviate this concern, we consider a relaxed but natural DP notion (for recommendation systems) called joint differential privacy (Kearns et al., 2014). Consider an algorithm $\mathcal{A}$ that produces individual outputs $Y_i$ for each user $i$, i.e., the $i$-th row of preference matrix $Y$. Joint DP ensures that for each user $i$, the output of $\mathcal{A}$ for all other users (denoted by $Y_{-i}$) does not reveal “much” about the preferences of user $i$. That is, the recommendations made to all the users except the $i$-th user do not depend significantly upon the $i$-th user’s preferences. Although not mentioned explicitly, previous works on DP matrix completion (McSherry & Mironov, 2009; Liu et al., 2015) strive to ensure joint DP. Formal definitions are provided in Section 2.

Granularity of privacy: DP protects the information about a user in the context of presence or absence of her data record. Prior works on DP matrix completion (McSherry & Mironov, 2009; Liu et al., 2015), and its close analogue, low-rank approximation (Blum et al., 2005; Chan et al., 2011; Hardt & Roth, 2012; Dwork et al., 2013; Hardt & Roth, 2013), have considered different variants of the notion of a data record. Some have considered a single entry in the matrix $Y^*$ as a data record (resulting in entry-level privacy), whereas others have considered a more practical setting where the complete row is a data record (resulting in user-level privacy). In this work, we present all our results in the strictly harder user-level privacy setting. To ensure a fair comparison, we present the results of prior works in the same setting.

1.1. Problem definition: Matrix completion

The goal of a low-rank matrix completion problem is to estimate a low-rank (or a convex relaxation of bounded nuclear norm) matrix $Y^* \in \mathbb{R}^{m \times n}$, having seen only a small number of entries from it. Here, $m$ is the number of users, and $n$ is the number of items. Let $\Omega = \{(i,j) \subseteq [m] \times [n]\}$ be the index set of the observed entries from $Y^*$, and let $P_\Omega : \mathbb{R}^{m \times n} \rightarrow \mathbb{R}^{m \times n}$ be a matrix operator s.t. $P_\Omega(Y)_{ij} = Y_{ij}$ if $(i,j) \in \Omega$, and 0 otherwise. Given, $P_\Omega(Y^*)$, the objective is to output a matrix $Y$ such that the following generalization error, i.e., the error in approximating a uniformly random entry from the matrix $Y^*$, is minimized:

$$F(Y) = \mathbb{E}_{(i,j) \sim \text{unif}[m] \times [n]}((Y_{ij} - Y^*_{ij})^2).$$

Generalization error captures the ability of an algorithm to predict unseen samples from $Y^*$. We would want the generalization error to be $o(1)$ in terms of the problem parameters when $\Omega = o(mn)$. Throughout the paper, we will assume that $m > n$.

1.1.1. Our contributions

In this work, we provide the first joint DP algorithm for low-rank matrix completion with formal non-trivial error bounds, which are summarized in Tables 1 and 2. At a high level, our key result can be summarized as follows:

Informal Theorem 1.1 (Corresponds to Corollary 3.1). Assume that each entry of a hidden matrix $Y^* \in \mathbb{R}^{m \times n}$ is in $[-1,1]$, and there are $\sqrt{n}$ observed entries per user. Also, assume that the nuclear norm of $Y^*$ is bounded by $O(\sqrt{mn})$, i.e., $Y^*$ has nearly constant rank. Then, there exist $(\epsilon, \delta)$-joint differentially private algorithms that have $o(1)$ generalization error as long as $m = \omega(n^{5/4})$.

In other words, even with $\sqrt{n}$ observed ratings per user, we obtain asymptotically the correct estimation of each entry of $Y^*$ on average, as long as $m$ is large enough. The sample complexity bound dependence on $m$ can be strengthened by making additional assumptions, such as incoherence, on $Y^*$. See the supplementary material for details.

Our algorithm is based on two important ideas: a) using local and global computation, b) using the Frank-Wolfe method as a base optimization technique.

Local and global computation: The key idea that defines our algorithm, and allows us to get strong error bounds under joint DP is splitting the algorithm into two components:
**global and local.** Recall that each row of the hidden matrix $Y^*$ belongs to an individual user. The global component of our algorithm computes statistics that are aggregate in nature (e.g., computing the correlation across columns of the revealed matrix $P_{\Omega}(Y^*)$). On the other hand, the local component independently fine-tunes the statistics computed by the global component to generate accurate predictions for each user. Since the global component depends on the data of all users, adding noise to it (for privacy) does not significantly affect the accuracy of the predictions. (McSherry & Mironov 2009, Liu et al. 2015) also exploit a similar idea of segregating the computation, but they do not utilize it formally to provide non-trivial error bounds.

**Frank-Wolfe based method:** We use the standard nuclear norm formulation (Recht 2011, Shalev-shwartz et al. 2011, Iewari et al. 2011, Candes & Recht 2012) for the matrix completion problem:

$$\min_{\|Y\|_{nuc} \leq k} \hat{F}(Y),$$

where $\hat{F}(Y) = \frac{1}{|\Omega|} \|P_{\Omega}(Y^* - Y^*)\|_F^2$. $\|Y\|_{nuc}$ is the sum of singular values of $Y$, and the underlying hidden matrix $Y^*$ is assumed to have nuclear norm of at most $k$. Note that we denote the empirical solution of a solution of $\hat{F}(Y)$ throughout the paper. We use the popular Frank-Wolfe algorithm (Frank & Wolfe 1956, Jaggi & Sulovsky 2010) as our algorithmic building block. At a high-level, FW computes the solution to (2) as a convex combination of rank-one matrices, each with nuclear norm at most $k$. These matrices are added iteratively to the solution.

Our main contribution is to design a version of the FW method that preserves Joint DP. That is, if the standard FW algorithm decides to add matrix $u \cdot v^T$ during an iteration, our private FW computes a noisy version of $v \in \mathbb{R}^n$ via its global component. Then, each user computes the respective element of $u \in \mathbb{R}^n$ to obtain her update. The noisy version of $v$ suffices for the Joint DP guarantee, and allows us to provide the strong error bound in Theorem 1.1 above.

We want to emphasize that the choice of FW as the underlying matrix completion algorithm is critical for our system. FW updates via rank-one matrices in each step. Hence, the error due to noise addition in each step is small (i.e., proportional to the rank), and allows for an easy decomposition into the local-global computation model. Other standard techniques like proximal gradient descent based techniques (Cai et al. 2010b, Lin et al. 2019) can involve nearly full-rank updates in an iteration, and hence might incur large error, leading to arbitrary inaccurate solutions. Note that though a prior work (Talwar et al. 2015) has proposed a DP Frank-Wolfe algorithm for high-dimensional regression, it was for a completely different problem in a different setting where the segregation of computation into global and local components was not necessary.

**Private singular vector of sparse matrices using Oja’s method:** Our private FW requires computing a noisy covariance matrix which implies $\Omega(n^2)$ space/time complexity for $n$ items. Naturally, such an algorithm does not scale to practical recommendation systems. In fact, this drawback exists even for standard private PCA techniques (Dwork et al. 2013). Using insights from the popular Oja’s method, we provide a technique (see Algorithm 2) that has a linear dependency on $n$ as long as the number of ratings per user is small. Moreover, the performance of our private FW method isn’t affected by using this technique.

**SVD-based method:** In the supplementary material, we also extend our technique to a singular value decomposition (SVD) based method for matrix completion/factorization. Our utility analysis shows that there are settings where this method outperforms our FW-based method, but in general it can provide a significantly worse solution. The main goal is to study the power of the simple SVD-based method, which is still a popular method for collaborative filtering.

**Empirical results:** Finally, we show that along with providing strong analytical guarantees, our private FW also performs well empirically. In particular, we show its efficacy on benchmark collaborative filtering datasets like Jester (Goldberg et al. 2001), MovieLens (Harper & Konstan 2015), the Netflix prize dataset (Bennett et al. 2007), and the Yahoo! Music recommender dataset (Yahoo 2011). Our algorithm consistently outperforms (in terms of accuracy) the existing state-of-the-art DP matrix completion methods (SVD-based method by McSherry & Mironov 2009), and a variant of projected gradient descent (Cai et al. 2010b, Bassily et al. 2014b, Abadi et al. 2016).

**1.2. Comparison to prior work**

As discussed earlier, our results are the first to provide non-trivial error bounds for DP matrix completion. For comparing different results, we consider the following setting of the hidden matrix $Y^* \in \mathbb{R}^{m \times n}$ and the set of released entries $\Omega$: i) $|\Omega| \approx m \sqrt{n}$, ii) each row of $Y^*$ has an $\ell_2$ norm of $\sqrt{n}$, and iii) each row of $P_{\Omega}(Y^*)$ has $\ell_2$-norm at most $n^{1/4}$, i.e., $\approx \sqrt{n}$ random entries are revealed for each row. Furthermore, we assume the spectral norm of $Y^*$ is at most $O(\sqrt{mn})$, and $Y^*$ is rank-one. Note that these conditions are satisfied by a matrix $Y^* = u \cdot v^T$ where $u_i, v_j \in [-1, 1]$ (as long as the number of ratings per user is small).

In Table 1, we provide a comparison based on the sample complexity, i.e., the number of users $m$ and the number of observed samples $|\Omega|$ needed to attain a generalization error of $o(1)$. We compare our results with the best non-private algorithm for matrix completion based on nuclear norm minimization (Shalev-shwartz et al. 2011), and the prior work on DP matrix completion (McSherry & Mironov 2009, Liu et al. 2015). We see that for the same $|\Omega|$, the
sample complexity on $m$ increases from $\omega(n)$ to $\omega(n^{5/4})$ for our FW-based algorithm. While McSherry and Mironov [2009], Liu et al. [2015] work under the notion of Joint DP as well, they do not provide any formal accuracy guarantees.

**2. Background: Notions of privacy**

Let $D = \{d_1, \ldots, d_m\}$ be a dataset of $m$ entries. Each entry $d_i$ lies in a fixed domain $\mathcal{T}$, and belongs to an individual $i$, whom we refer to as an agent in this paper. Furthermore, $d_i$ encodes potentially sensitive information about agent $i$. Let $\mathcal{A}$ be an algorithm that operates on dataset $D$, and produces a vector of $m$ outputs, one for each agent $i$ and from a set of possible outputs $\mathcal{S}$. Formally, let $\mathcal{A} : \mathcal{T}^m \rightarrow \mathcal{S}^m$. Let $D_{-i}$ denote the dataset $D$ without the entry of the $i$-th agent, and similarly $\mathcal{A}_{-i}(D)$ be the set of outputs without the output for the $i$-th agent. Also, let $(d_i; D_{-i})$ denote the dataset obtained by adding data entry $d_i$ to the dataset $D_{-i}$. In the following, we define both standard differential privacy and joint differential privacy, and contrast them.

**Definition 2.1** (Standard differential privacy [Dwork et al., 2006]). An algorithm $\mathcal{A}$ satisfies $(\epsilon, \delta)$-differential privacy if for any agent $i$, any two possible values of data entry $d_i, d'_i \in \mathcal{T}$ for agent $i$, any tuple of data entries for all other agents, $D_{-i} \in \mathcal{T}^{m-1}$, and any output $S \in \mathcal{S}^m$, we have

$$
\mathbb{Pr}\left[\mathcal{A}(d_i; D_{-i}) \in S\right] \leq e^\epsilon \mathbb{Pr}\left[\mathcal{A}(d'_i; D_{-i}) \in S\right] + \delta.
$$

At a high-level, an algorithm $\mathcal{A}$ is $(\epsilon, \delta)$-standard DP if for any agent $i$ and dataset $D$, the output $\mathcal{A}(D)$ and $D_{-i}$ do not reveal “much” about her data entry $d_i$. For reasons mentioned in Section 1, our matrix completion algorithms provide privacy guarantee based on a relaxed notion of DP, called joint differential privacy, which was initially proposed in [Kearns et al., 2014]. At a high-level, an algorithm $\mathcal{A}$ preserves $(\epsilon, \delta)$-joint DP if for any agent $i$ and dataset $D$, the output of $\mathcal{A}$ for the other $(m - 1)$ agents (denoted by $\mathcal{A}_{-i}(D)$) and $D_{-i}$ do not reveal “much” about her data entry $d_i$. Such a relaxation is necessary for matrix completion because an accurate completion of the row of an agent can reveal a lot of information about her data entry. However, it is still a very strong privacy guarantee for an agent even if every other agent colludes against her, as long as she does not make the predictions made to her public.

**Definition 2.2** (Joint differential privacy [Kearns et al., 2014]). An algorithm $\mathcal{A}$ satisfies $(\epsilon, \delta)$-joint differential privacy if for any agent $i$, any two possible values of data entry $d_i, d'_i \in \mathcal{T}$ for agent $i$, any tuple of data entries for all other agents, $D_{-i} \in \mathcal{T}^{m-1}$, and any output $S \in \mathcal{S}^{m-1}$,

$$
\mathbb{Pr}\left[\mathcal{A}_{-i}(d_i; D_{-i}) \in S\right] \leq e^\epsilon \mathbb{Pr}\left[\mathcal{A}_{-i}(d'_i; D_{-i}) \in S\right] + \delta.
$$

In this paper, we consider the privacy parameter $\epsilon$ to be a small constant ($\approx 0.1$), and $\delta < 1/m$. There are semantic reasons for such choice of parameters (Kasiviswanathan & Smith, 2008), but that is beyond the scope of this work.
3. Private matrix completion via Frank-Wolfe

Recall that the objective is to solve the matrix completion problem (defined in Section 1) under Joint DP. A standard modeling assumption is that $Y^*$ is nearly low-rank, leading to the following empirical risk minimization problem (Keshavan et al. 2010; Jain et al. 2013; Jin et al. 2016):

$$\min_{\|Y\|_F \leq k} \frac{1}{2} \|P_{\Omega} (Y - Y^*)\|_F^2,$$

where $k \ll \min(m, n)$.

As this is a challenging non-convex optimization problem, a popular approach is to relax the rank constraint to a nuclear-norm constraint, i.e., $\min_{\|G\|_{nuc} \leq k} \hat{F}(Y)$. To this end, we use the FW algorithm (see the supplementary material for more details) as our building block. FW is a popular conditional gradient algorithm in which the current iterate is updated as: $Y(t) \leftarrow (1 - \eta) Y(t-1) + \eta \cdot G$, where $\eta$ is the step size, and $G$ is given by:

$$\arg \min_{\|G\|_{nuc} \leq k} \left\langle G, \nabla Y(t-1)^* \hat{F}(Y) \right\rangle.$$

Note that the optimal solution to the above problem is $G = -kuv^T$, where $(\lambda, u, v)$ are the top singular components of $A(t-1) = P_{\Omega} (Y(t-1) - Y^*)$. Also, the optimal $G$ is a rank-one matrix.

A block schematic of this idea is presented in Figure 1.

**Algorithm 1** Private Frank-Wolfe algorithm

**function** Global Component $A_{global}$ (**Input**- privacy parameters: $(\epsilon, \delta)$ s.t. $\epsilon < 2 \log(1/\delta)$, total number of iterations: $T$, bound on $\|P_{\Omega}(Y^*)\|_2$: $L$, failure probability: $\beta$, number of users: $m$, number of items: $n$)

$$\sigma \leftarrow L^2 \sqrt{64 \cdot T \log(1/\delta)} / \epsilon, \tilde{v} \leftarrow \{0\}^n, \lambda \leftarrow 0$$

**for** $t \in [T]$ **do**

$$W(t) \leftarrow \{0\}^{n \times n}, \hat{X}^t \leftarrow \lambda + \sqrt{\sigma \log(n/\beta)n^{1/4}}$$

**for** $i \in [m]$ **do**

$$W(t) \leftarrow W(t) + A_{local}(i, \tilde{v}, \hat{X}^t, T, t, L)$$  

$$W(t) \leftarrow W(t) + N(0, \sigma^2)$$

Define $\Pi_{L, \Omega}(M)_{i,j} = \min \left\{ \frac{L}{\|P_{\Omega}(M)\|_2}, 1 \right\} \cdot M_{i,j}$

$$Y_i(t) \leftarrow \Pi_{L, \Omega} \left( (1 - \frac{1}{T}) Y_i(t-1) - \frac{\eta \lambda}{L} \tilde{u}_i(v)^T \right)$$

$$A_i(t) \leftarrow P_{\Omega} \left( Y_i(t) - Y^* \right)$$

**if** $t = T$, Output $Y_i^{(T)}$ as prediction to user $i$ and **stop**

**else** Return $A_i^{(t)} \hat{A}_i^{(t)}$ to $A_{global}$

**end function**

**Noisy rank-one update**: Observe that $v$ and $\lambda$, the statistics computed in each iteration of $A_{global}$, are aggregate statistics that use information from all rows of $Y^*$. This ensures that they are noise tolerant. Hence, adding sufficient noise can ensure standard DP (Definition 2.1) for $A_{global}$. Since $\lambda$ is a noisy estimate of $\lambda$, the second term in computing $\hat{X}^t$ in Algorithm 1 is due to a bound on the spectral norm of the Gaussian noise matrix. We use this bound to control the error introduced in the computation of $\lambda$.

**Figure 1.** Block schematic describing the two functions $A_{local}$ and $A_{global}$ of Algorithm 1. The solid boxes and arrows represent computations that are privileged and without external access, and the dotted boxes and arrows represent the unprivileged computations.

**Algorithmic ideas**: In order ensure Joint DP and still have strong error guarantees, we develop the following ideas. These ideas have been formally compiled into Algorithm 1. Notice that both the functions $A_{global}$ and $A_{local}$ in Algorithm 1 are parts of the Private FW technique, where $A_{global}$ consists of the global component, and each user runs $A_{local}$ at her end to carry out a local update. Throughout this discussion, we assume that $\max_{i \in [m]} \|P_{\Omega}(Y_i^*)\|_2 \leq L$.

**Splitting the update into global and local components**: One can equivalently write the Frank-Wolfe update as follows:

$$Y(t) \leftarrow (1 - \eta) Y(t-1) - \frac{\eta \lambda}{L} A(t-1)^{\top} v v^{\top},$$

where $A(t-1)$, $v$, and $\lambda$ are defined as above. Note that $v$ and $\lambda^2$ can also be obtained as the top right eigenvector and eigenvalue of $A(t-1)^{\top} A(t-1) = \sum_{i=1}^{m} A_i(t-1)^{\top} A_i(t-1)$, where $A_i(t-1) = P_{\Omega} (Y_i(t-1) - Y^*_i)$ is the $i$-th row of $A(t-1)$. We will use the global component $A_{global}$ in Algorithm 1 to compute $v$ and $\lambda$. Using the output of $A_{global}$, each user (row) $i \in [m]$ can compute her local update (using $A_{local}$) as follows:

$$Y_i(t) \leftarrow (1 - \eta) Y_i(t-1) - \frac{\eta \lambda}{L} P_{\Omega} (Y_i(t-1) - Y^*_i) v v^{\top}. \quad (3)$$
the final objective is to satisfy Joint DP (Definition 2.2), the local component $A_{\text{local}}$ can compute the update for each user (corresponding to (3)) without adding any noise.

Controlling norm via projection: In order to control the amount of noise needed to ensure DP, any individual data entry (here, any row of $Y^*$) should have a bounded effect on the aggregate statistic computed by $A_{\text{global}}$. However, each intermediate computation $Y^t(i)$ in (3) can have high $\ell_2$-norm even if $\|P_{\Omega}(Y^t(i))\|_2 \leq L$. We address this by applying a projection operator $\Pi_{L,\Omega}$ (defined below) to $Y^t(i)$, and compute the local update as $\Pi_{L,\Omega}(Y^t(i))$ in place of (3). $\Pi_{L,\Omega}$ is defined as follows: For any matrix $M$, $\Pi_{L,\Omega}(M)$ ensures that any row of the “zeroed out” matrix $P_{\Omega}(M)$ does not have $\ell_2$-norm higher than $L$. Formally, $\Pi_{L,\Omega}(M)_{i,j} = \min \left\{ \frac{L}{\|P_{\Omega}(M)\|_2}, 1 \right\} \cdot M_{i,j}$, for all entries $(i,j)$ of $M$. In our analysis, we show that this projection operation does not increase the error.

3.1. Privacy and utility analysis

Theorem 3.1. Algorithm 7 satisfies $(\epsilon, \delta)$-joint DP.

We defer the proof to the supplementary material. The proof uses standard DP properties of Gaussian noise addition from (Bun & Steinke 2016). The requirement $\epsilon \leq 2 \log (1/\delta)$ in the input of Algorithm 7 is due to a reduction of a Concentrated DP guarantee to a standard DP guarantee. We now show that the empirical risk of our algorithm is close to the optimal as long as the number of users $m$ is “large”.

Theorem 3.2 (Excess empirical risk guarantee). Let $Y^*$ be a matrix with $\|Y^*\|_{\text{nuc}} \leq k$, and $\max_{i \in [m]} \|P_{\Omega}(Y^*)\|_2 \leq L$. Let $Y^{(T)}$ be a matrix, with its rows being $Y^{(T)}_i$ for all $i \in [m]$, computed by function $A_{\text{local}}$ in Algorithm 7 after $T$ iterations. If $\epsilon \leq 2 \log (\frac{1}{L})$, then with probability at least $2/3$ over the outcomes of Algorithm 7 the following is true:

$$\tilde{F}(Y^{(T)}) = O \left( \frac{k^2}{|\Omega|T} + \frac{kT^{1/4}L \sqrt{nL}}{\sqrt{\log nL}} \right).$$

Furthermore, if $T = \tilde{O} \left( \frac{k^{4/5}L^{1/5}}{\sqrt{nL}} \right)$, then $\tilde{F}(Y^{(T)}) = \tilde{O} \left( \frac{k^{4/5}L^{1/5}}{\sqrt{nL}} \right)$ after hiding poly-logarithmic terms.

We defer the proof to the supplementary material. At a high-level, our proof combines the noisy eigenvector estimation error for Algorithm 7 with an upper bound on the empirical risk of the FW algorithm. Also, note that the first term in the bound corresponds to the standard FW convergence error, while the second term can be attributed to the noise added for DP which directly depends on $T$. We also compute the optimal number of iterations required to minimize the empirical risk. Finally, the rank of $Y^{(T)}$ is at most $T$, but its nuclear-norm is bounded by $k$. As a result, $Y^{(T)}$ has low generalization error (see Section 3.1.1).

Remark 1. We further illustrate our empirical risk bound by considering a simple setting: let $Y^*$ be a rank-one matrix with $Y^*_{ij} \in [-1, 1]$ and $|\Omega| = m \sqrt{n}$. Then $k = \mathcal{O}(\sqrt{mn})$, and $L = \mathcal{O}(n^{1/4})$, implying an error of $\Theta(\sqrt{mn}^{-2/5})$ hiding the privacy parameter $\epsilon$; in contrast, a trivial solution like $Y = 0$ leads to $O(1)$ error. Naturally, the error increases with $n$ as there is more information to be protected. However, it decreases with a larger number of users $m$ as the presence/absence of a user has lesser effect on the solution with increasing $m$. We leave further investigation into the dependency of the error on $m$ for future work.

Remark 2. Our analysis does not require an upper bound on the norm of $Y^*$ (as stated in Theorem 3.2): we would instead incur an additional error of $\min_{\|Y\|_{\text{nuc}} \leq K} \|P_{\Omega}(Y^* - Y)\|_2^2$. Moreover, consider a similar scenario as in Remark 1 but $|\Omega| = mn$, i.e., all the entries of $Y^*$ are revealed. In such a case, $L = O(\sqrt{n})$, and the problem reduces to that of standard low-rank matrix approximation of $Y^*$. Note that our result here leads to an error bound of $\tilde{O} \left( \frac{n^{1/3}}{m^{1/6}} \right)$, while the state-of-the-art result by (Hardt & Roth 2015) leads to an error bound of $O(1)$ due to being in the much stricter standard DP model.

3.1.1. Generalization error guarantee

We now present a generalization error (defined in Equation 1) bound which shows that our approach provides accurate prediction over unknown entries. For obtaining our bound, we use Theorem 1 from (Srebro & Shraibman 2005) (provided in the supplementary material for reference). Also, the output of Private FW (Algorithm 7) has rank at most $T$, where $T$ is the number of iterations. Thus, replacing $T$ from Theorem 3.2, we get the following:

Corollary 3.1. Generalization Error. Let $\|Y^*\|_{\text{nuc}} \leq k$ for a hidden matrix $Y^*$, and $\|P_{\Omega}(Y^*)\|_2 \leq L$ for every row $i$ of $Y^*$. If we choose the number of rounds in Algorithm 7 to be $O \left( \frac{k^{4/3}}{\log^{1/6}(m + n)} \right)$, the data samples in $\Omega$ are drawn u.a.r. from $[m] \times [n]$, and $\epsilon \leq 2 \log (\frac{1}{L})$, then with probability at least $2/3$ over the outcomes of the algorithm and choosing $\Omega$, the following is true for the final completed matrix $Y^*$:

$$F(Y^*) = \tilde{O} \left( \frac{k^{4/3}L \log^{1/4}}{\sqrt{\epsilon |\Omega| \log^2 (m + n)}} + \frac{k \sqrt{m + n}}{|\Omega|} \right)^{2/3}.$$
This is slightly higher than the bound in the non-private setting by (Shalev-shwartz et al., 2011), where \( m = \omega(n) \) is sufficient to get generalization error \( o(1) \). Also, as the first term in the error bound pertains to DP, it decreases with a larger number of users \( m \), and increases with \( n \) as it has to preserve privacy of a larger number of items. In contrast, the second term is the matrix completion error decreases with \( n \). This is intuitive, as a larger number of movies enables more sharing of information between users, thus allowing a better estimation of preferences \( Y^* \). However, just increasing \( m \) may not always lead to a more accurate solution (for example, consider the case of \( n = 1 \)).

**Remark 4.** The guarantee in Corollary 3.1 is for uniformly random \( \Omega \), but using the results of (Shamir & Shalev-Shwartz 2011), it is straightforward to extend our results to any i.i.d. distribution over \( \Omega \). Moreover, we can extend our results to handle strongly convex and smooth loss functions instead of the squared loss considered in this paper.

### 3.2. Efficient PCA via Oja’s Algorithm

Algorithm 1 requires computing the top eigenvector of \( \tilde{W}^{(t)} = W^{(t)} + N^{(t)} \), where \( W^{(t)} = \sum_i (A_i^{(t)})^T A_i^{(t)} \) and \( N^{(t)} \) is a random noise matrix. However, this can be a bottleneck for computation as \( N^{(t)} \) itself is a dense \( n \times n \) matrix, implying a space complexity of \( \Omega(n^2 + mk) \), where \( k \) is the maximum number of ratings provided by a user. Similarly, standard eigenvector computation algorithms will require \( O(mk^2 + n^2) \) time (ignoring factors relating to rate of convergence), which can be prohibitive for practical recommendation systems with large \( n \). We would like to stress that this issue plagues even standard DP PCA algorithms (Dwork et al. 2013), which have quadratic space-time complexity in the number of dimensions.

We tackle this by using a stochastic algorithm for the top eigenvector computation that significantly reduces both space and time complexity while preserving privacy. In particular, we use Oja’s algorithm ( Jain et al. 2016), which computes top eigenvectors of a matrix with a stochastic access to the matrix itself. That is, if we want to compute the top eigenvector of \( W^{(t)} \), we can use the following updates:

\[
\hat{v}_t = (I + \eta X_t)\hat{v}_{t-1}, \quad \hat{v}_t = \hat{v}_t / \|\hat{v}_t\|_2 \tag{4}
\]

where \( \hat{v}_t = v_t \). For example, we can update \( \hat{v}_t \) using \( X_t = W^{(t)} + N^{(t)} \) where each entry of \( N^{(t)} \) is sampled i.i.d. from a Gaussian distribution calibrated to ensure DP. Even this algorithm in its current form does not decrease the space or time complexity as we need to generate a dense matrix \( N^{(t)} \) in each iteration. However, by observing that \( N^{(t)} v = g_t \sim \mathcal{N}(0, \sigma^2 I) \) where \( v \) is independent of \( N^{(t)} \), we can now replace the generation of \( N^{(t)} \) by the generation of a vector \( g_t \), thus reducing both the space and time complexity of our algorithm. The computation of each update is significantly cheaper as long as \( mk \ll n^2 \), which is the case for practical recommendation systems as \( k \) tends to be fairly small there (typically on the order of \( \sqrt{n} \)).

Algorithm 2 provides a pseudocode of the eigenvector computation method. The computation of the approximate eigenvector \( \hat{V}_t \) and the eigenvalue \( \lambda^2_t \) in it is DP (directly follows via the proof of Theorem 3.1). The next natural question is how well can \( \hat{V}_t \) approximate the behavior of the top eigenvector of the non-private covariance matrix \( W^{(t)} \) to this end, we provide Theorem 3.3 below that analyzes Oja’s algorithm, and shows that the Rayleigh quotient of the approximate eigenvector is close to the top eigenvalue of \( W^{(t)} \). In particular, using Theorem 3.3, along with the fact that in our case, \( \sqrt{V} = \sigma^2 n \), we have \( \|A(t)\|_2^2 \leq \|A(t)\hat{V}_t\|_2^2 + O(\sqrt{\sigma n} \log(\eta/\beta)) \) with high probability (w.p. \( \geq 1 - \beta^2 \)), where \( \hat{V}_t \) is the output of Algorithm 2.

**Theorem 3.3 (Based on Theorem 3 in (Allen-Zhu & Li 2017)).** Let \( X_1, X_2, \ldots, X_t \) be sampled i.i.d. such that \( \mathbb{E}X_i = W = A^T A \). Moreover, let \( \nu = \max\{\|\mathbb{E}(X_i - W)(X_i - W)\|_2, \|\mathbb{E}(X_i - W)(X_i - W)^T\|_2\} \), and \( \eta = \frac{1}{\sqrt{\nu}} \). Then, the \( t \)-th iterate of Oja’s Algorithm (Update 4), i.e., \( \hat{V}_t \), satisfies (w.p. \( \geq 1 - 1/\text{poly}(\Gamma) \)):

\[
\hat{V}_t^T W \hat{V}_t \geq \|W\|_2 - O\left(\sqrt{\frac{1}{\Gamma}} + \frac{\|W\|_2}{\sqrt{\nu}}\right).
\]

**Comparison with Private Power Iteration (PPI) method (Hardt & Roth 2013):** Private PCA via PPI provides utility guarantees dependent on the gap between the top and the \( k \)th eigenvalue of the input matrix \( A \) for some \( k > 1 \), whereas private Oja’s utility guarantee is gap-independent.

### 4. Experimental evaluation

We now present empirical results for Private FW (Algorithm 1) on several benchmark datasets, and compare its
performance to state-of-the-art methods like (McSherry & Mironov, 2009), and private as well as non-private variant of the Projected Gradient Descent (PGD) method (Cai et al., 2010c; Bassily et al., 2014a; Abadi et al., 2016). In all our experiments, we see that private FW provides accuracy very close to that of the non-private baseline, and almost always significantly outperforms both the private baselines.

Datasets: As we want to preserve privacy of every user, and the output for each user is n-dimensional, we can expect the private recommendations to be accurate only when \( m \gg n \) (see Theorem 3.1). Due to this constraint, we conduct experiments on the following datasets: 1) Synthetic: We generate a random rank-one matrix \( Y^* = uv^T \) with unit \( l_\infty \)-norm, \( m = 500K \), and \( n = 400 \), 2) Jester: This dataset contains \( n = 100 \) jokes, and \( m \approx 73K \) users, 3) MovieLens10M (Top 400): We pick the \( n = 400 \) most rated movies from the MovieLens10M dataset, resulting in \( m \approx 70K \) users, 4) Netflix (Top 400): We pick the \( n = 400 \) most rated movies from the Netflix prize dataset, resulting in \( m \approx 474K \) users, and 5) Yahoo! Music (Top 400): We pick the \( n = 400 \) most rated songs from the Yahoo! music dataset, resulting in \( m \approx 995K \) users. We rescale the ratings to be from 0 to 5 for Jester and Yahoo! Music.

Procedure: For all datasets, we randomly sample \( 1\% \) of the given ratings for measuring the test error. For experiments with privacy, for all datasets except Jester, we randomly select at most \( \xi = 80 \) ratings per user to get \( P_\xi(Y^*) \). We vary the privacy parameter \( \epsilon \in [0, 1, 5] \) but keep \( \delta = 10^{-6} \), thus ensuring that \( \delta < \frac{1}{m} \) for all datasets. Moreover, we report results averaged over 10 independent runs.

Note that the privacy guarantee is user-level, which effectively translates to an entry-level guarantee of \( \epsilon_{\text{entry}} = \frac{\epsilon_{\text{user}}}{m} \), i.e., \( \epsilon_{\text{entry}} \in [0.00125, 0.0625] \) as \( \epsilon_{\text{user}} \in [0, 1, 5] \).

Non-private baseline: We find that non-private FW and non-private PGD converge to the same accuracy after tuning, and hence, we use this as our baseline.

Private baselines: To the best of our knowledge, only (McSherry & Mironov, 2009) and (Liu et al., 2015) address the user-level DP matrix completion problem. While we present an empirical evaluation of the ‘SVD after cleansing method’ from the former, we refrain from comparing to the latter. We also provide a comparison with private PGD (pseudocode provided in the supplementary material).

We elaborate on the data normalization and the parameter choices for all algorithms in the supplementary material.

Results: Figure 2 shows the results of our experiments. Even though all the considered private algorithms satisfy Joint DP, our private FW method almost always incurs a significantly lower test RMSE than the two private baselines. Note that although non-private PGD provides similar empirical accuracy as non-private FW, the difference in performance for their private versions can be attributed to the noise being calibrated to a rank-one update for our private Frank-Wolfe.

Figure 2. Root mean squared error (RMSE) vs. \( \epsilon \), on (a) synthetic, (b) Jester, (c) MovieLens10M, (d) Netflix, and (e) Yahoo! Music datasets, for \( \delta = 10^{-6} \). A legend for all the plots is given in (f).
