Abstract

Computing the partition function $Z$ of a discrete graphical model is a fundamental inference challenge. Since this is computationally intractable, variational approximations are often used in practice. Recently, so-called gauge transformations were used to improve variational lower bounds on $Z$. In this paper, we propose a new gauge-variational approach, termed WMBE-G, which combines gauge transformations with the weighted mini-bucket elimination (WMBE) method. WMBE-G can provide both upper and lower bounds on $Z$, and is easier to optimize than the prior gauge-variational algorithm. We show that WMBE-G strictly improves the earlier WMBE approximation for symmetric models including Ising models with no magnetic field. Our experimental results demonstrate the effectiveness of WMBE-G even for generic, non-symmetric models.

1 INTRODUCTION

Graphical Models (GMs) express the factorization of the joint multivariate probability distribution over subsets of variables via graphical relations among them. GMs have been developed in information theory [1, 2], physics [3, 4, 5, 6, 7], artificial intelligence [8], and machine learning [9, 10]. For a GM, computing the partition function $Z$ (the normalization constant) is a fundamental inference task of great interest. However, this task is known to be computationally intractable in general: it is #P-hard even to approximate [11].

Variational approaches frame the inference task as an optimization problem, which is typically solved approximately. Key challenges for variational methods are to scale efficiently with the number of variables; and to try to provide guaranteed upper or lower bounds on $Z$.

Popular variational methods include: the mean-field (MF) approximation [6], which provides a lower bound on $Z$; the tree-reweighted (TRW) approximation [12], which provides an upper bound; and belief propagation (BP) [13], which often performs well but provides neither an upper nor lower bound in general. Other variational methods have been investigated for providing lower bounds [14, 15, 16, 17] or upper bounds [15, 16, 17] for approximating $Z$.

Methods using reparametrizations [18], gauge transformations (GT) [19, 20] or holographic transformations (HT) [21, 22] have been explored. These methods each consider modifying the base GM by transforming the potential factors in various ways, aiming to simplify the inference task, while keeping the partition function $Z$ unchanged. We call these methods collectively $Z$-invariant methods. See [23, 24, 25] for discussions of the differences and relations between these methods.

An approach to combine variational and $Z$-invariant methods was recently introduced by [26], yielding a lower bound on $Z$. They proposed gauge-variational optimization formulations built upon MF and BP, incorporating the generic IPOPT solver [27] as an essential inner optimization routine. Here we introduce a new gauge-variational optimization approach, using variational methods other than MF and BP, and employing a specialized solver for inner optimization which is more efficient than IPOPT. Further, our approach yields lower and upper bounds on $Z$.

Contribution. We develop a new family of gauge-variational algorithms combining the methods of gauge transformations (GTs) and weighted mini-bucket elimination (WMBE) [16]. The significance of our new approach, which we call WMBE-G, is twofold:

C1. We introduce optimization formulations which provide both upper and lower bounds of $Z$ by general-
Gauged Mini-Bucket Elimination for Approximate Inference

C2. We propose a novel optimization solver alternating between gauges and factors to minimize (or maximize) the proposed objectives, and demonstrate its computational advantages. We remark that the earlier optimization approaches in [26] required ‘non-negativity’ constraints which are tricky to handle, while we do not. [26] addresses the challenge using the generic IPOPT solver with the log-barrier method, but it is not. [26] addresses the challenge using the generic IPOPT solver with the log-barrier method, but it is not. 

Our experimental results show that WMBE-G has superior performance in comparison with other known algorithms, including WMBE. We remark that the main contribution of WMBE [16] was to introduce Hölder weights to improve the original mini-bucket elimination (BE) bound [29], whereas we additionally optimize gauges for even better performance. In our experiments, we observe that the contribution of Hölder weights is relatively marginal compared to gauges in optimizing the BE bound (see Section 4 for more details). Namely, we found that gauges are more crucial than Hölder weights for better approximation to $Z$, while the computational costs of optimizing them are similar. In this paper, we mainly focus on WMBE-G using the Hölder inequality to obtain an upper bound on $Z$, but a lower bound can be similarly derived using the reverse Hölder inequality (see Section 2.3).

2 PRELIMINARIES

2.1 Factor-graph GM. We consider an undirected, bipartite factor graph $G = (V, E)$ with vertices $V = X \cup F$ comprising variables $X$ and factors $F$, and edges between variable and factor nodes $E \subseteq X \times F$. Each random variable $x_v \in X$ is discrete, taking values in $\{1, \ldots, d\}$. The distribution factorizes as follows:

$$p(x) = \frac{1}{Z} \prod_{\alpha \in F} f_\alpha(x_\alpha).$$

Here, $F = \{f_\alpha\}_{\alpha \in F}$ is a set of non-negative functions called factors, and $x_\alpha$ is the subset of variables for factor

The transformed GM with respect to the gauges $G = \{G_{va} : (v, \alpha) \in E\}$ consists of modified factors $\{\tilde{f}_\alpha : \alpha \in F\}$ computed as follows:

$$\tilde{f}_\alpha(x_\alpha; G_\alpha) = \sum_{x_\alpha'} f_\alpha(x_\alpha') \prod_{v \in N(\alpha)} G_{va}(x_v, x'_v),$$

where $G_\alpha = \{G_{va} : v \in N(\alpha)\}$. Here, the gauges must satisfy the following gauge constraints:

$$G_{va}^T G_{vb} = I, \quad \forall v \in X,$$
where I is the identity matrix and \(N(v) = \{\alpha, \beta\}\) (recall that we assume \(|N(v)| = 2\)). With these constraints, the partition function is known to be invariant under the transformation \([19]\) \([20]\), i.e.,

\[
Z = \sum_{\mathbf{x}} \prod_{\alpha \in \mathcal{F}} f_{\alpha}(\mathbf{x}_{\alpha}) = \sum_{\mathbf{x}} \prod_{\alpha \in \mathcal{F}} \tilde{f}_{\alpha}(\mathbf{x}_{\alpha}; \mathbf{G}_{\alpha}).
\]

Thus gauges lead to the transformed distribution \(p(\mathbf{x}; \mathbf{G}) = \prod_{\alpha \in \mathcal{F}} \tilde{f}_{\alpha}(\mathbf{x}_{\alpha}; \mathbf{G}_{\alpha})/Z\). We remark that it might be invalid when \(\tilde{f}_{\alpha}(\mathbf{x}_{\alpha}; \mathbf{G}_{\alpha})\) is negative. Nevertheless, even in this case, the partition function invariance still holds. We provide an example of a gauge transformation in the Supplement.

### 2.3 Weighted Mini-Bucket Elimination

**Bucket (or variable) elimination (BE) \([31]\) \([32]\) is a method for computing the partition function exactly based on directly summing out the variables sequentially. First, BE assumes a fixed elimination ordering \(o = [v_1, \cdots, v_n]\) among variables nodes \(v \in X\). Then, BE groups factors by placing each factor \(f_{\alpha}\) in the “bucket” \(B_v\) of its earliest argument \(v \in N(\alpha)\) appearing in the elimination order \(o\). Next, BE eliminates the variable by marginalizing the product of factors in the bucket, i.e.,

\[
\tilde{f}_{B_v}(\mathbf{x}_{B_v}) = \sum_{v} \prod_{f_{\alpha} \in B_v} f_{\alpha}(\mathbf{x}_{\alpha}) \quad \forall \mathbf{x}_{B_v},
\]

where \(\mathbf{x}_{B_v} = [x_u : u \in \text{var}(B_v), u \neq v]\) and \(\text{var}(B_v)\) indicates the subset of variables in the bucket. Finally, the newly generated function \(\tilde{f}_{B_v}\) is inserted into another bucket corresponding to its earliest argument in the elimination order. This process is easily seen as applying a distributive property: groups of factors corresponding to buckets are summed out sequentially, and then the newly created factor (without the eliminated variable) is assigned to another bucket.

The computational cost of BE is exponential in the number of uneliminated variables in the bucket, i.e., the *induced width* \([1]\) of the graph given the elimination order. BE is summarized in Algorithm 1.

**Algorithm 1** BE for computing \(Z\)

1. **Input:** GM on graph \(G = (V, E)\) with \(V = (X, F)\) and factors \(\mathcal{F} = \{f_{\alpha}\}_{\alpha \in \mathcal{F}}\) and elimination order \(o = [v_1, \cdots, v_n]\).
2. **Initialize** \(\mathcal{F}' \leftarrow \mathcal{F}\).
3. **for** \(v \in o\) **do**
   4. Set \(B_v \leftarrow \{f_{\alpha} | \alpha \in \mathcal{F}, v \in N(\alpha)\}\).
   5. **Generate** new factor by:
      \[
      \tilde{f}_{B_v}(\mathbf{x}_{B_v}) = \sum_{x_v} \prod_{f_{\alpha} \in B_v} f_{\alpha}(\mathbf{x}_{\alpha}), \quad \forall \mathbf{x}_{B_v}.
      \]
6. **Update** \(\mathcal{F}' \leftarrow \mathcal{F}' \cup \{\tilde{f}_{B_v}\} - B_v\).
7. **end for**
8. **Output:** \(Z = \prod_{f_{\alpha} \in \mathcal{F}'} f_{\alpha}\)

---

**Mini-bucket elimination (MBE) \([25]\)** and **weighted mini-bucket elimination (WMBE) \([10]\)** approximate BE by splitting computation of each bucket into several “mini-buckets”, where WMBE additionally makes use of Hölder’s inequality \([33]\). Since MBE is a special case of WMBE (by choosing extreme Hölder weights), here we focus on providing background for WMBE.

Let \(\{\psi_i(x), i = 1, \cdots, m\}\) be some functions defined on discrete variable \(x\), and \(\mathbf{w} = [w_1, \cdots, w_n]\) be a vector of Hölder weights. We define a weighted absolute summation, \(\sum w_i \psi_i(x) := (\sum x^{|\psi_i(x)|/w_i})^{w_i}\).

Equivalently, \(\sum w_i \psi_i(x)\) is the Schatten \(p\)-norm with \(p = 1/w_i\). If \(w_i > 0\) for all \(i \geq 1\), then Hölder’s inequality implies that

\[
\sum_{x} \prod_{i=1}^{m} \psi_i(x) \leq \prod_{i=1}^{m} \sum_{x} \psi_i(x),
\]

where \(w_0 = \sum w_i\). If only one weight is positive, e.g., \(w_1 > 0\) and \(w_i < 0\) for all \(i > 1\), we have the reverse Hölder’s inequality:

\[
\sum_{x} \prod_{i=1}^{m} \psi_i(x) \geq \prod_{i=1}^{m} \sum_{x} \psi_i(x).
\]

WMBE modifies BE by applying Hölder’s inequality whenever the size of a bucket, i.e., length of \(\mathbf{x}_{B_v}\), exceeds some given parameter called *bound*. In this case, WMBE splits the bucket into multiple ‘mini-buckets’, and weighted absolute summation is evaluated sequentially in place of BE, i.e.,

\[
\sum_{x_v} \prod_{f_{\alpha} \in B_v} |f_{\alpha}(x_{\alpha})| \leq \sum_{x_v} \prod_{f_{\alpha} \in B_v^r} f_{\alpha}(x_{\alpha}),
\]

for all \(x_{B_v^r}\), where Hölder weights satisfy \(\sum w_r = 1, w_r > 0, B_v = \bigcup B_v^r,\) and \(B_v^r\) is disjoint for all \(r\). We then generate multiple new factors by:

\[
\tilde{f}_{B_v^r}(\mathbf{x}_{B_v^r}) = \sum_{x_v} \prod_{f_{\alpha} \in B_v^r(x_{\alpha})}, \quad \forall \mathbf{x}_{B_v^r},
\]

and insert into other buckets. By construction, WMBE yields an upper bound for the partition function \(Z\). One
Gauged Mini-Bucket Elimination for Approximate Inference

In this section, we describe our gauge optimization scheme WMBE-G to improve the previous WMBE bound, yielding guarantee upper bound approximations for the partition function $Z$. Our scheme improves the standard WMBE bound by searching over the large family of gauge transformed (possibly invalid) GMs to find the tightest WMBE bound possible.

3.1 Key Optimization Formulation

In order to describe the optimization formulation for tightening the WMBE bound, we first observe that (8) can be reformulated into

$$
\sum_{x_v} \prod_{f \in B_v} |f(x_v)| \leq \sum_{x_v^{(1)}} \cdots \sum_{x_v^{(R_v)}} \prod_{r=1}^{R_v} \prod_{\alpha \in F_r} f_{\alpha}(x_v^{(r)} ; x_{\alpha \backslash v}),
$$

(7)

where $x_{\alpha \backslash v} = \{x_u : u \in N(\alpha), u \neq v\}$. While notation is complex, this is simply applying the distributive property on the right hand side of (8). The procedure can be seen as ‘splitting’ variable from $x_v$ to $x_v^{(1)}, \ldots, x_v^{(R_v)}$ and its associated node from $v$ to $v^{(1)}, \ldots, v^{(R_v)}$ so that factors no longer share the split variable. We remark that under Forney-style GMs, $R_v \leq 2$ since exactly 2 factors are associated with a variable. After repeatedly applying the inequality, we arrive at the following WMBE bound, termed weighted partition function:

$$
Z \leq Z_{\text{WMBE}} = \prod_{f \in \mathcal{F}} \bar{w}_f \prod_{\alpha \in \mathcal{F}} f_{\alpha}(\bar{x}_\alpha). 
$$

(8)

In (8), $\bar{x} = [\bar{x}_1, \ldots, \bar{x}_n]$ and $\bar{w} = [\bar{w}_1, \ldots, \bar{w}_n]$ indicate the ‘split’ version of variables and associated Hölder weights, indexed by appearance of associated node in the modified elimination order $\bar{\sigma} = \left[1^{(1)}, \ldots, v^{(R_1)}, \ldots, 1^{(1)}, \ldots, v^{(R_n)}\right]$. Therefore, the WMBE bound can be seen as a weighted absolute summation over product of factors in a new GM. However, unlike the original partition function, the weighted absolute summation is tractable with respect to $\text{ibound}$ since at most $d^{\text{ibound}}$ terms are counted for each weighted absolute summation, or equivalently variable elimination of mini-buckets. Finally, we are able to present our main optimization formulation:

$$
\begin{align*}
\text{minimize}_{G} & \quad \sum_{\bar{x}_n} \cdots \sum_{\bar{x}_1} \prod_{\alpha \in \mathcal{F}} f_{\alpha}(\bar{x}_\alpha; G_{\alpha}), \\
\text{subject to} & \quad G_{v \alpha}^T G_{v \beta} = I, \quad \forall \ v \in X, N(v) = \{\alpha, \beta\}.
\end{align*}
$$

(9)

3.2 Algorithm Description

We now describe an efficient algorithm to optimize (9). First, the gauge constraint can be removed simply by expressing one (of the two) gauges in terms of the other, e.g., $G_{v \beta}$ via $(G_{v \alpha})^{-1}$. Then, (9) can be optimized via any type of unconstrained optimization solver. Here, we optimize gauges by gradient descent followed by additional updates on factor values.

To this end, we initialize gauges by identity matrices, which immediately yields the original WMBE bound from (8) since $f_{\alpha}(x_\alpha) = f_{\alpha}(x_\alpha; I_{\alpha})$, where $I_{\alpha} = [G_{v \alpha} = I : (v, \alpha) \in E]$. Next, under expressing gauges via one another, i.e., $G_{v \beta} \leftarrow (G_{v \alpha})^{-1}$, we update each gauge element by gradient descent for minimization of the weighted
log partition function upper bound \( \log Z_{\text{WMBE}} \) as follows:

\[
G_{\text{WMBE}}(x', x'_v) \leftarrow G_{\text{WMBE}}(x', x'_v) - \mu \frac{\partial \log Z_{\text{WMBE}}}{\partial G_{\text{WMBE}}(x', x'_v)}
\]

\[
\frac{\partial \log Z_{\text{WMBE}}}{\partial G_{\text{WMBE}}(x', x'_v)} = \sum_{\hat{x}_{\alpha \\ \beta}} q(\hat{x}_{\alpha \\ \beta}, x'_v) f_\alpha(\hat{x}_{\alpha \\ \beta}, x'_v) - \sum_{\hat{x}_{\beta \\ \alpha}} q(\hat{x}_{\beta \\ \alpha}, x'_v) f_\beta(\hat{x}_{\beta \\ \alpha}, x'_v)
\]

where \( \mu \) is the step size and \( \hat{x}_{\alpha \\ \beta} = [x_u : u \in N(\alpha), u \neq v] \) and \( q \) is an ‘auxiliary distribution’ defined as

\[
q(\hat{x}) = \prod_{k=1}^{\hat{n}} q(\hat{x}_k | \hat{x}_{k+1:n})
\]

\[
q(\hat{x}_k | \hat{x}_{k+1:n}) \propto \left( \sum_{\hat{x}_{\alpha \\ \beta}} \sum_{\hat{x}_{\beta \\ \alpha}} f_\alpha(\hat{x}_{\alpha \\ \beta}, \hat{x}_{\beta \\ \alpha}) \right)^{-1/\hat{w}_k}
\]

We also update \( G_{\alpha \beta} \leftarrow (G_{\alpha \beta}^{-1}) \) and the value of associated factors by the gauge-transformed factors, i.e.,

\[
f_\alpha(x_\alpha) \leftarrow \hat{f}_\alpha(x_\alpha; G_{\alpha})
\]

and similarly for \( f_\beta \). Finally, for the next iteration, we reset \( G_{\text{WMBE}} \leftarrow \mathbb{I} \).

The above update leads to an improved WMBE bound, which can be repeated for better bounds (until convergence). Each iteration \( t = 1, \ldots, T \) results in a sequence of gauges \( G^{(t)} \) obtained by \( \mathbb{I} \), and factors \( f^{(t)}_a \) obtained by \( \mathbb{I} \) can be expressed as

\[
f^{(t)}_a(x_\alpha) = \hat{f}^{(t)}_a(x_\alpha; G^{(t)}_{a})
\]

where \( f^{(t)}_a = f_a \) is the original GM factor, and \( G^{(t)}_{a} \) consists of gauges \( G^{(t)}_{\alpha \beta} = C^{(t+1)}_{\alpha \beta} G^{(t)}_{\alpha \beta} \cdots G^{(t)}_{\alpha \beta} \) for \( v \in N(\alpha) \). We remark that one can use naïve gradient descent, i.e., update gauges only (without resetting to identity matrices), instead of factors as in \( \mathbb{I} \). However, by utilizing the additional factor updates, the gradient formulation is simplified and redundant computations of gauge transformations are reduced. We summarize the above update procedure in Algorithm 3.

Furthermore, one can utilize ideas from \( \mathbb{I} \) in order to improve the efficiency and power of the proposed optimization. First, computation of auxiliary marginals \( q(x_\alpha) \) in \( \mathbb{I} \) can be efficiently carried out by a message-passing scheme proposed by the authors. Moreover, one can jointly optimize the Hölder weights \( \hat{w} \) in addition to \( G \) using the auxiliary distribution during optimization of \( \mathbb{I} \). In our experiments, we utilize both the message-passing algorithm and the joint optimization involving \( \hat{w} \) using the log-gradient step proposed by the authors.

Finally, we remark that the elimination order and bucket split strategy might be another freedom that one may exploit in order to tighten the WMBE bound. However, their optimizations are hard (see \( \mathbb{I} \)). Hence, we choose the elimination order arbitrarily in our experiments. For the bucket split strategy, if one assumes Forney-style GMs, any strategy reduces into a fixed split process, i.e., whenever \( \text{ibound} \) is exceeded, a variable \( x \) is always split in two parts \( x^{(1)}, x^{(2)} \), and adjacent factors are assigned separately.

Algorithm 3 Gauged WMBE for bounding \( Z \)

\begin{enumerate}
\item \textbf{Input:} GM on graph \( G = (V, E) \) with \( V = (X, F) \), factors \( F = \{f_\alpha\}_{\alpha \in F} \), elimination order \( o = [v_1, \ldots, v_n] \) and bound on bucket size \text{ibound}.
\end{enumerate}

\begin{enumerate}
\item \( F' \leftarrow F \)
\item \( \hat{o} \leftarrow \emptyset, \hat{w} \leftarrow \emptyset \).
\item Initialize by \( \hat{o} = \emptyset, \hat{w} = \emptyset \).
\item for \( v \in o \) do
\item \( B_v \leftarrow \{f_\alpha | f_\alpha \in F, v \in N(\alpha)\} \)
\item Partition \( B_v \) into \( R_v \) subgroups \( \{B'_v\}_{\alpha \in F} \) such that \( |\text{var}(B'_v)| \leq \text{ibound} \) for all \( r \).
\item Assign weights \( w_1, \ldots, w_{R_v} \) while satisfying \( \sum_r w_r = 1 \).
\item for \( r \leftarrow 1, \ldots, R_v \) do
\item Generate a new factor by:
\item \( f_{B'_v}(x_{B'_v}) = \sum_{x_{B'_v}} \prod_{f_\alpha(x_\alpha), \forall x_{B'_v}} f_\alpha(x_\alpha) \).
\item \( F' \leftarrow F' \cup \{f_{B'_v} - B_v\} \)
\item end for
\item Extend \( \hat{o} \) by \( [v^{(1)}, \ldots, v^{(R_v)}] \).
\item Extend \( \hat{w} \) by \( [w_1, \ldots, w_{R_v}] \).
\item end for
\item Initialize by \( G_{\text{WMBE}} = \mathbb{I} \) for all \( (v, \alpha) \in E \).
\item for \( t = 1, 2, \ldots, T \) do
\item for \( v \in X \) with \( N(v) = \{\alpha, \beta\} \) do
\item Update \( G_{\text{WMBE}} \) by \( \mathbb{I} \).
\item \( G_{v \beta} \leftarrow (G_{v \beta}^{-1}) \)
\item Set \( f_\alpha(x_\alpha) \leftarrow \hat{f}_\alpha(x_\alpha; G_{\alpha}) \) and \( f_\beta(x_\beta) \leftarrow \hat{f}_\beta(x_\beta; G_{\beta}) \) for all \( x_\alpha, x_\beta \).
\item end for
\item end for
\item end for
\item \textbf{Output:} \( Z_{\text{WMBE-G}} = \prod_{f \in F} f \)
\end{enumerate}

### 3.3 Relation to Previous Work

Hölder’s inequality holds even for negative-valued functions, so we do not need to put any additional constraint on non-negativity of factors, e.g., \( \hat{f}_\alpha(x_\alpha; G_{\alpha}) \geq 0 \). Thus, invalid gauged transformed GMs are allowed for \( \mathbb{I} \). This contrasts with the earlier work of \( \mathbb{I} \), where additional non-negativity constraints were needed to restrict the gauge transformations considered. Consequently, to our knowl-
edge, our formulation is the first to explore the full range of freedom in gauge transformations when combined with methods of variational inference for GMs. Further, avoiding these non-negativity constraints simplifies our optimization procedure enabling an approach which scales much better than that of [20].

We emphasize that our optimization formulation (9) is a strict generalization of the approach of [15] which optimizes the WMBE bound with respect to reparameterization of GMs. Specifically, the GM reparameterized with respect to reparameterization parameters \( \boldsymbol{\theta} = \{\theta_{v\alpha} : (v, \alpha) \in E\} \) consists of factors:

\[
\tilde{f}_{\alpha}(x_{\alpha}; \theta_{\alpha}) = \prod_{v \in N(\alpha)} \exp(\theta_{v\alpha}(x_{i}))f_{\alpha}(x_{\alpha}),
\]

where \( \theta_{\alpha} = \{\theta_{v\alpha} : v \in N(\alpha)\} \). Here, the reparameterization parameter \( \theta_{v\alpha} \) is constrained to satisfy the following constraint:

\[
\exp(\theta_{v\alpha}(x_{v}) + \theta_{v\beta}(x_{v})) = 1 \quad \forall \ v \in X, x_{v},
\]

where \( N(v) = \{\alpha, \beta\} \). With this constraint, it is easy to check that such transformations are distribution-invariant [18] and form a strict subset of gauge transformations. Alternatively, when gauges are restricted to diagonal matrices with non-negative elements, [2] and [3] match [12] and [13], respectively. Therefore, optimizing (9) is guaranteed to perform no worse than that of [16]. Formally, we provide the following analytic class of GMs where gauge transformations are expected to perform strictly better than reparameterizations. Here, we say a function of binary variables is symmetric if its value is invariant under a ‘flipping’ of all variables in its scope, e.g., \( f_{\alpha}(2, 1, 2) = f_{\alpha}(1, 2, 1) \).

Theorem 1. Consider a GM over binary variables (i.e., \( d = 2 \)) where every factor \( f_{\alpha} \) is symmetric. Then, \( \theta = \{\theta_{v\alpha}(x_{v}) = 0, \forall (v, \alpha) \in E, x_{v}\} \) is always a solution of the following optimization:

\[
\min_{\theta} \sum_{x_{1}} \cdots \sum_{x_{1}} \prod_{\alpha \in F} \tilde{f}_{\alpha}(x_{\alpha}; \theta_{\alpha}),
\]

subject to \( \exp(\theta_{v\alpha}(x_{v}) + \theta_{v\beta}(x_{v})) = 1 \quad \forall \ v \in X, x_{v}. \)

The proof of Theorem 1 is given in the Supplement. It shows that for symmetric GMs, e.g., the Ising model with no magnetic field, reparameterization is impossible to improve the WMBE bound. On the other hand, gauges are expected to improve it as we explain in what follows. We first remark that the optimality condition for reparameterization is equivalent to the zero gradient condition for diagonal elements of gauges, i.e., \( \sum_{x_{\alpha}} \eta(x_{\alpha}) = \sum_{x_{\beta}} \eta(x_{\beta}) \), which aims to match the auxiliary marginals of variables split by WMBE. Under symmetric models, variables are indistinguishable from an auxiliary marginals point of view, which leads to Theorem 1.

On the other hand, the zero gradient condition for non-diagonal gauges is harder to match since it takes local conditional dependency into account, e.g., considers \( f_{\alpha}(x_{\alpha} \setminus v, x'_{\alpha})/f_{\alpha}(x_{\alpha} \setminus v, x''_{\alpha}) \) upon evaluating the gradient. For symmetric GMs, the above reasoning for reparameterization fails since variables are distinguishable after conditioning, e.g., \( f_{\alpha}(x_{\alpha} \setminus v, x'_{v}) \neq f_{\alpha}(x_{\alpha} \setminus v, x''_{v}) \). Namely, optimal gauges believably have non-diagonal elements. Indeed, in all our experiments, gauge transformations significantly outperform reparameterizations.

4 EXPERIMENTS

In this section, we report experimental results on performance of our proposed algorithms for the task of upper bounding the partition function \( Z \).

4.1 Setup

Experiments were conducted with three family of GMs: (i) Ising models on a \( 10 \times 10 \) grid graph (non-toroidal) with 180 factors/100 variables; (ii) Forney-style GMs on the 3-regular graph with 180 factors/270 variables; and (iii) Linkage dataset from UAI 2014 Inference Competition [34].

Figure 3: Illustration of Ising grid GM (left), its equivalent Forney-style GM (middle) and 3-regular graph (right) of interest. Factors surrounding the selected lattice (blue, dashed) are contracted into a single factor, and then uniform single potentials (grey, filled) are added for variables of degree 1.

(i) Ising models. Ising models were defined with mixed interactions (spin glasses):

\[
p(x) = \frac{1}{Z} \exp \left( \sum_{v \in X} \phi_{v}x_{v} + \sum_{(u,v) \in E} \phi_{uv}x_{u}x_{v} \right),
\]

where \( x_{u} \in \{-1, 1\} \) and \( \phi_{v} \sim \mathcal{N}(0, 0.1), \phi_{uv} \sim \mathcal{N}(0, T) \). Here, \( T \geq 0 \) is the ‘interaction strength’ parameter that controls the degree of interactions between variables. When \( T = 0 \), variables are independent. As \( T \) grows, the inference task is typically harder.

Note that this Ising model is not in Forney-style form, with variables adjacent to at most 4 pairwise factors. Hence, to apply our gauge optimization framework, we generate an equivalent Forney-style GM using the transformation introduced in [30]: this maps any classical lattice model (allow-
ing for magnetic fields/singleton potentials) into an equivalent Forney-style model. At a high level, the transformation chooses disjoint lattices to cover the whole graph, then contracts each lattice into a single factor. Levin and Nave [30] showed that one can always choose the lattice smartly so that each vertex is covered exactly twice, resulting in a Forney-style GM (see Figure 3 for details). Notably, this GM has relatively low induced width of 14, thus the partition function can be computed exactly in reasonable time (though still computationally hard) by using BE.

(ii) 3-regular Forney-style GMs. We considered 3-regular Forney-style GMs with log-factors drawn from normal distribution, i.e., log \( f_\alpha(x_\alpha) \sim N(0, T) \). Again, \( T \geq 0 \) is the interaction strength parameter. In this case, we would like to choose graphs so that the induced width is high and the partition function is hard to compute. To this end, we aligned factors in a cycle, and assigned variables (edges) between adjacent factors in the cycle as well as those in the opposite side if it. See Figure 3 for its illustration. This choice gives high induced width, e.g., naïvely applying BE by eliminating variables between adjacent factors in clockwise elimination order results in bucket size \( 2^{|V|/2 + 2} \).

(iii) UAI Linkage dataset. Finally, we consider a family of real-world models from the UAI 2014 Inference Competition, namely the Linkage (genetic linkage) dataset. Specifically, the family consists of GMs with average of 949.94 variables with averaged maximum cardinality \( \max_{i \in V} |X_i| = 4.95 \) and 727.35 non-singleton hyper-edges with averaged maximum size \( \max_{a \in E} |a| = 4.47 \). Since GMs in Linkage dataset were not of Forney-style form, we constructed an equivalent Forney-style GM as in Figure 1.

Comparing approaches. We compared our gauged algorithm WMBE-G, i.e. optimizing the WMBE bound jointly with gauges and Hölder weights, to earlier methods considered in [16]: the unoptimized WMBE bound (‘WMBE’), its optimized versions with respect to Hölder weights \( w \) and/or reparameterizations \( \theta \) (‘WMBE-w’, ‘WMBE-θ’ and ‘WMBE-wθ’). Further, we also ran the following popular baselines for computing upper bounds on \( Z \): standard mini-bucket elimination (‘MBE’) and tree re-weighted belief propagation (‘TRBP’) [12]. Finally, for fair comparisons in Ising grid GMs, we additionally compared to MBE and TRBP run on the original Ising grid GM (MBE-Ising and TRBP-Ising) in order to validate whether the forementioned GM transformation to a Forney-style model is ‘favored’ towards gauge optimization.

Further details. Hölder weights \( w \) and reparameterizations \( \theta \) were updated using projected gradients and log-derivatives respectively, as proposed in [16]. Step sizes for gradients were chosen as 0.01, 0.1, 0.1 for optimizing each of gauge, Hölder weights, and reparameterizations, respectively. These were chosen empirically for ‘easy’ convergence in our experiments – there exists room for tuning.
Next, we consider experiments on specific instances of the UAI dataset. We observe that WMBE-wG always outperforms other approaches significantly for 3-regular GMs and UAI dataset, where it outperforms even WMBE-related bounds (via gradient descent methods) for an initial 150 iterations. Then, we change the parameter to optimize further (e.g., $G \to \theta$) for another 300 iterations to observe the additional benefit from optimizing the second parameter. The running times per iteration for all parameters are comparable. We observe that $G$ methods perform very well, which is particularly impressive since we use a small step size for gauges. Overall, observed performance gains may be ranked as: gauges > weights > reparameterization for Ising grid GMs; and gauges > reparameterization > weights for 3-regular GMs. Gauge optimization is critical for the best performance in all experiments. As expected, $wG$ yields the best results. For 3-regular GMs, gauge optimization alone is almost optimal.

5 Conclusion

We developed a new gauge-variational approach to yield guaranteed bounds on the partition functions of GMs by jointly optimizing variational parameters and gauge transformations. Our approach has better scaling characteristics than other recent state-of-the-art methods, and should be of significant practical value.
