Abstract

The recognition network in deep latent variable models such as variational autoencoders (VAEs) relies on amortized inference for efficient posterior approximation that can scale up to large datasets. However, this technique has also been demonstrated to select suboptimal variational parameters, often resulting in considerable additional error called the amortization gap. To close the amortization gap and improve the training of the generative model, recent works have introduced an additional refinement step that applies stochastic variational inference (SVI) to improve upon the variational parameters returned by the amortized inference model. In this paper, we propose the Buffered Stochastic Variational Inference (BSVI), a new refinement procedure that makes use of SVI’s sequence of intermediate variational proposal distributions and their corresponding importance weights to construct a new generalized importance-weighted lower bound. We demonstrate empirically that training the variational autoencoders with BSVI consistently out-performs SVI, yielding an improved training procedure for VAEs.

1 Introduction

Deep generative latent-variable models are important building blocks in current approaches to a host of challenging high-dimensional problems including density estimation [1, 2, 3], semi-supervised learning [4, 5] and representation learning for downstream tasks [6, 7, 8, 9]. To train these models, the principle of maximum likelihood is often employed. However, maximum likelihood is often intractable due to the difficulty of marginalizing the latent variables. Variational Bayes addresses this by instead providing a tractable lower bound of the log-likelihood, which serves as a surrogate target for maximization. Variational Bayes, however, introduces a per sample optimization subroutine to find the variational proposal distribution that best matches the true posterior distribution (of the latent variable given an input observation). To amortize the cost of this optimization subroutine, the variational autoencoder introduces an amortized inference model that learns to predict the best proposal distribution given an input observation [1, 10, 11, 12].

Although the computational efficiency of amortized inference has enabled latent variable models to be trained at scale on large datasets [13, 14], amortization introduces an additional source of error in the approximation of the posterior distributions if the amortized inference model fails to predict the optimal proposal distribution. This additional source of error, referred to as the amortization gap [15], causes variational autoencoder training to further deviate from maximum likelihood training [15, 16].

To improve training, numerous methods have been developed to reduce the amortization gap. In this paper, we focus on a class of methods [17, 18, 19] that takes an initial proposal distribution predicted by the amortized inference model and refines this initial distribution with the application of Stochastic Variational Inference (SVI) [20]. Since SVI applies gradient ascent to iteratively update the proposal distribution, a byproduct of this procedure is a trajectory of proposal distributions \( (q_0, \ldots, q_k) \) and their corresponding importance weights \( (w_0, \ldots, w_k) \). The intermediate distributions are discarded, and only the last distribution \( q_k \) is retained for updating the generative model. Our key insight is that the intermediate importance weights can be repurposed to further improve training. Our contributions are as follows

1. We propose a new method, Buffered Stochastic

Proceedings of the 22nd International Conference on Artificial Intelligence and Statistics (AISTATS) 2019, Naha, Okinawa, Japan. PMLR: Volume 89. Copyright 2019 by the author(s).
**Variational Inference** (BSVI), that takes advantage of the intermediate importance weights and constructs a new lower bound (the BSVI bound).

2. We show that the BSVI bound is a special instance of a family of generalized importance-weighted lower bounds.

3. We show that training variational autoencoders with BSVI consistently outperforms SVI, demonstrating the effectiveness of leveraging the intermediate weights.

Our paper shows that BSVI is an attractive replacement of SVI with minimal development and computational overhead.

## 2 Background and Notation

We consider a latent-variable generative model $p_θ(x, z)$ where $x \in \mathcal{X}$ is observed, $z \in \mathcal{Z}$ is latent, and $θ$ are the model’s parameters. The marginal likelihood $p_θ(x)$ is intractable but can be lower bounded by the evidence lower bound (ELBO)

$$\ln p_θ(x) \geq \mathbb{E}_{q(z)} \left[ \ln \frac{p_θ(x, z)}{q(z)} \right] = \mathbb{E}_{q(z)} \ln w(z),$$

which holds for any distribution $q(z)$. Since the gap of this bound is exactly the Kullback-Leibler divergence $D(q(z) \| p_0(z \| x))$, $q(z)$ is thus the variational approximation of the posterior. Furthermore, by viewing $q$ as a proposal distribution in an importance sampler, we refer to $w(z) = \frac{p_θ(x, z)}{q(z)}$ as an unnormalized importance weight. Since $w(z)$ is a random variable, the variance can be reduced by averaging the importance weights derived from i.i.d samples from $q(z)$. This yields the Importance-Weighted Autonencer (IWAE) bound [21],

$$\ln p_θ(x) \geq \mathbb{E}_{z_1, \ldots, z_k \sim q, i \sim \mathcal{U}} \left[ \ln \frac{1}{k} \sum_{i=1}^{k} w(z_i) \right] \geq \text{ELBO},$$

which admits a tighter lower bound than the ELBO [21, 22].

### 2.1 Stochastic Variational Inference

The generative model can be trained by jointly optimizing $q$ and $θ$ to maximize the lower bound over the data distribution $p(x)$. Supposing the variational family $Q = \{q(\cdot \| \lambda)\}_{\lambda \in \Lambda}$ is parametric and indexed by the parameter space $\Lambda$ (e.g. a Gaussian variational family indexed by mean and covariance parameters), the optimization problem becomes

$$\max_{θ} \mathbb{E}_{p(x)} \left[ \max_{\lambda} \mathbb{E}_{q(z; \lambda)} \ln w(z \| \lambda, θ) \right].$$

where importance weight $w$ is now

$$w(z \| \lambda, θ) = \frac{p_θ(x, z)}{q(z \| \lambda)},$$

For notational simplicity, we omit the dependency on $x$. For a fixed choice of $θ$ and $x$, [17] proposed to optimize $λ$ via gradient ascent, where one initializes with $λ_0$ and takes successive steps of

$$λ_{i+1} \leftarrow λ_i + η \nabla_λ \text{ELBO},$$

for which the ELBO gradient with respect to $λ_i$ can be approximated via Monte Carlo sampling as

$$\nabla_λ \text{ELBO} \approx \frac{1}{m} \sum_{j=1}^{m} \nabla_λ \ln w(z_{λ_i}(e^{(j)}) \| λ_i, θ)$$

where $z_{λ_i}(e^{(j)}) = q(z \| λ_i)$ is reparameterized as a function of $λ_i$ and a base distribution $p_0$. We note that $k$ applications gradient ascent generates a trajectory of variational parameters $(λ_0, \ldots, λ_k)$, where we use the final parameter $λ_k$ for the approximation. Following the convention in [20], we refer to this procedure as Stochastic Variational Inference (SVI).

### 2.2 Amortized Inference Suboptimality

The SVI procedure introduces an inference subroutine that optimizes the proposal distribution $q(z \| λ)$ per sample, which is computationally costly. [1, 10] observed that the computational cost of inference can be amortized by introducing an inference model $f_φ : \mathcal{X} \rightarrow \Lambda$, parameterized by $φ$, that directly seeks to learn the mapping $x \mapsto λ^*$ from each sample $x$ to an optimal $λ^*$ that solves the maximization problem

$$λ^* = \arg\max_{λ} \mathbb{E}_{q(z \| λ)} \ln \frac{p_θ(x, z)}{q(z \| λ)}.$$

This yields the amortized ELBO optimization problem

$$\max_{θ, φ} \mathbb{E}_{p(x)} \left[ \mathbb{E}_{q(z; f_φ(x))} \ln \frac{p_θ(x, z)}{q(z \| f_φ(x))} \right],$$

where $q(z \| f_φ(x))$ can be concisely rewritten (with a slight abuse of notation) as $q_φ(z \| x)$ to yield the standard variational autoencoder objective [1].

While computationally efficient, the influence of the amortized inference model on the training dynamics of the generative model has recently come under scrutiny [15, 17, 18, 16]. A notable consequence of amortization is the amortization gap

$$D(q_φ(z \| x) \| p_0(z \| x)) - D(q(z \| λ^*) \| p_0(z \| x))$$

which measures the additional error incurred when the amortized inference model is used instead of the optimal $λ^*$ for approximating the posterior [15]. A large amortization gap can present a potential source of concern since it introduces further deviation from the maximum likelihood objective [16].
2.3 Amortization-SVI Hybrids

To close the amortization gap, [17] proposed to blend amortized inference with SVI. Since SVI requires one to initialize $\lambda_0$, a natural solution is to set $\lambda_0 = f_\phi(x)$. Thus, SVI is allowed to fine-tune the initial proposal distribution found by the amortized inference model and reduce the amortization gap. Rather than optimizing $\theta, \phi$ jointly with the amortized ELBO objective Eq. (8), the training of the inference and generative models is now decoupled; $\phi$ is trained to optimize the amortized ELBO objective, but $\theta$ is trained to approximately optimize Eq. (3), where $\lambda^* = \lambda_k$ is approximated via SVI. To enable end-to-end training of the inference and generative models, [18] proposed to backpropagate through the SVI steps via a finite-difference estimation of the necessary Hessian-vector products. Alternatively, [19] adopts a learning-to-learn framework where an inference model iteratively outputs $\lambda_{i+1}$ as a function of $\lambda_i$ and the ELBO gradient.

3 Buffered Stochastic Variational Inference

![Figure 1: Idealized visualization of Buffered Stochastic Variational Inference. Double arrows indicate deterministic links, and single arrows indicate stochastic links that involve sampling. The dotted arrow from $x$ to $q_0$ denotes that the initial variational parameters are given by the encoder. For notational simplicity, we omitted the dependence of $q_{1..k}$ on $x$ and the model parameters $\phi, \theta$.](image)

In this paper, we focus on the simpler, decoupled training procedure described by [17] and identify a new way of improving the SVI training procedure (orthogonal to the end-to-end approaches in [18, 19]). Our key observation is that, as part of the gradient ascent estimation in Eq. (6), the SVI procedure necessarily generates a sequence of importance weights $(w_0, \ldots, w_k)$, where $w_i = w(z_i; \lambda_i, \theta)$. Since $(\ln w_k)$ likely achieves the highest ELBO, the intermediate weights $(w_0, \ldots, w_{k-1})$ are subsequently discarded in the SVI training procedure, and only $\nabla_{\theta, \Phi} \ln w_k$ is retained for updating the generative model parameters. However, if the preceding proposal distributions $(q_{k-1}, q_{k-2}, \ldots)$ are also reasonable approximations of the posterior, then it is potentially wasteful to discard their corresponding importance weights. A natural question to ask then is whether the full trajectory of weights $(w_0, \ldots, w_k)$ can be leveraged to further improve the training of the generative model.

Taking inspiration from IWAE’s weight-averaging mechanism, we propose a modification to the SVI procedure where we simply keep a buffer of the entire importance weight trajectory and use an average of the importance weights $\sum_i \pi_i w_i$ as the objective in training the generative model. The generative model is then updated with the gradient $\nabla_{\theta} \ln \sum_i \pi_i w_i$. We call this procedure Buffered Stochastic Variational Inference (BSVI) and denote $\ln \sum_i \pi_i w_i$ as the BSVI objective. We describe the BSVI training procedure in Algorithm 1 and contrast it with SVI training. For notational simplicity, we shall always imply initialization with an amortized inference model when referring to SVI and BSVI.

Algorithm 1 Training with Buffered Stochastic Variational Inference. We contrast training with SVI versus BSVI. We denote the stop-gradient operation with $\left\langle \cdot \right\rangle$, reflecting that we do not backpropagate through the SVI steps.

18: end for

$^3$For simplicity, we use the uniform-weighting $\pi_t = 1/(k+1)$ in our base implementation of BSVI. In Section 4.1, we discuss how to optimize $\pi$ during training.
Construct an unbiased estimate of the log-marginal-likelihood, which we denote the Generalized IWAE bound. Let $p(x, z) = \prod_{i=0}^{k} p(x, z_i)$ be a distribution where $z \in \mathcal{Z}$. Consider a joint proposal distribution $q(z_{0:k})$ over $\mathcal{Z}^k$. Let $\psi(i) \subseteq \{0, \ldots, k\} \setminus \{i\}$ for all $i$, and $\pi$ be a categorical distribution over $\{0, \ldots, k\}$. The following construction, which we denote the Generalized IWAE Bound, is a valid lower bound of the log-marginal-likelihood

$$\mathbb{E}_{q(z_{0:k})} \ln \sum_{i=0}^{k} \pi_i \frac{p(x, z_i)}{q(z_i \mid z_{\psi(i)})} \leq \ln p(x), \quad (10)$$

The proof follows directly from the linearity of expectation when using $q(z_{0:k})$ for importance-sampling to construct an unbiased estimate of $p_\theta(x)$, followed by application of Jensen’s inequality. A detailed proof is provided in Appendix A.

Notably, if $q(z_{0:k}) = \prod_i q(z_i)$, then Theorem 1 reduces to the IWAE bound. Theorem 1 thus provides a generalization of IWAE, where the samples drawn are potentially non-independently and non-identically distributed. Theorem 1 thus provides a way to construct new lower bounds on the log-likelihood whenever one has access to a set of non-independent samples.

In this paper, we focus on a special instance where a chain of samples is constructed from the SVI trajectory. We note that the BSVI objective can be expressed as

$$\mathbb{E}_{q(z_{0:k} \mid x)} \ln \sum_{i=0}^{k} \pi_i w_i = \mathbb{E}_{q(z_{0:k} \mid x)} \ln \sum_{i=0}^{k} \pi_i p_\theta(x, z_i) q(z_i \mid z_{\psi(i)}, x). \quad (11)$$

Note that since $\lambda_i$ can be deterministically computed given $(x, z_{<i})$, it is therefore admissible to interchange the distributions $q(z_i \mid z_{<i}, x) = q(z_i \mid \lambda_i)$. The BSVI objective is thus a special case of the Generalized IWAE bound, where $z_{\psi(i)} = z_{<i}$ with auxiliary conditioning on $x$. Hence, the BSVI objective is a valid lower bound of $\ln p_\theta(x)$; we now refer to it as the BSVI bound where appropriate.

In the following two subsections, we address two additional aspects of the BSVI bound. First, we propose a method for ensuring that the BSVI bound is tighter than the Evidence Lower Bound achievable via SVI. Second, we provide an initial characterization of BSVIs implicit sampling-importance-resampling distribution.

### 4.1 Buffer Weight Optimization

Stochastic variational inference uses a series of gradient ascent steps to generate a final proposal distribution $q(z \mid \lambda_k)$. As evident from Figure 2a, the parameter $\lambda_k$ is in fact a random variable. The ELBO achieved via SVI, in expectation, is thus

$$\mathbb{E}_{q(z, \lambda_k \mid x)} \ln \frac{p_\theta(x, z)}{q_\theta(z \mid \lambda_k)} = \mathbb{E}_{q(z_{0:k} \mid x)} \ln w_k, \quad (12)$$

where the RHS re-expresses it in notation consistent with Eq. (11). We denote Eq. (12) as the SVI bound. In general, the BSVI bound with uniform-weighting $\pi_i = 1/(k + 1)$ is not necessarily tighter than the SVI bound. For example, if SVI’s last proposal distribution exactly matches posterior $q_\theta(z) = p_\theta(z \mid x)$, then assigning equal weighting to across $(w_0, \ldots, w_k)$ would make the BSVI bound looser.

In practice, we observe the BSVI bound with uniform-weighting to consistently achieve a tighter lower bound than SVI’s last proposal distribution. We attribute this phenomenon to the effectiveness of

![Dependent proposal distributions](image1)

(a) Dependent proposal distributions

![Dependent samples](image2)

(b) Dependent samples

Figure 2: Graphical model for dependent proposal distributions and samples. When $\lambda_{i:k}$ is marginalized, the result is a joint distribution of dependent samples. For notational simplicity, the dependency on $\theta$ is omitted.
variance-reduction from averaging multiple importance weights—even when these importance weights are generated from dependent and non-identical proposal distributions.

To guarantee that the BSVI is tighter than the SVI bound, we propose to optimize the buffer weight $\pi$. This guarantees a tighter bound,

$$\max_{\pi} E_{q(z_{0:k} \mid x)} \ln \sum_{i=0}^{k} \pi_i w_i \geq E_{q(z_{0:k} \mid x)} \ln w_{i_0},$$  \hspace{1cm} (13)

since the SVI bound is itself a special case of the BSVI bound when $\pi = (0, \ldots, 0, 1)$. It is worth noting that Eq. (13) is concave with respect to $\pi$, allowing for easy optimization of $\pi$.

Although $\pi$ is a local variational parameter, we shall, for simplicity, optimize only a single global $\pi$ that we update with gradient ascent throughout the course of training. As such, $\pi$ is jointly optimized with $\theta$ and $\phi$.

4.2 Dependence-Breaking via Double-Sampling

![Figure 3: Graphical model for double sampling. Notice that the samples $z_{0:k}$ are now independent given $\lambda_{0:k}$ and $x$. Again the dependence on $\theta$ is omitted for notational simplicity.](image)

As observed in [20], taking the gradient of the log-likelihood with respect to $\theta$ results in the expression

$$\nabla_{\theta} \ln p_\theta(x) = E_{p_\theta(z \mid x)} \nabla_{\theta} \ln p_\theta(x, z).$$  \hspace{1cm} (14)

We note that gradient of the ELBO with respect to $\theta$ results in a similar expression

$$\nabla_{\theta} \text{ELBO}(x) = E_{q_\phi(z \mid x)} \nabla_{\theta} \ln p_\theta(x, z).$$  \hspace{1cm} (15)

As such, the ELBO gradient differs from log-likelihood gradient only in terms of the distribution applied by the expectation operator. To approximate the log-likelihood gradient, we wish to set $q_\phi(z \mid x)$ close to $p_\theta(z \mid x)$ under some divergence.

We now show what results from computing the gradient of the BSVI objective.

Lemma 1. The BSVI gradient with $\theta$ is

$$\nabla_{\theta} \text{BSVI}(x) = E_{q_{\text{air}}(z \mid x)} \nabla_{\theta} \ln p_\theta(x, z),$$  \hspace{1cm} (16)

where $q_{\text{air}}$ is a sampling-importance-resampling procedure defined by the generative process

$$z_{0:k} \sim q(z_{0:k} \mid x)$$  \hspace{1cm} (17)

$$i \sim r(i \mid z_{0:k})$$  \hspace{1cm} (18)

$$z \leftarrow z_i,$$  \hspace{1cm} (19)

and $r(i \mid z_{0:k}) = (\pi_i w_i) / (\sum_j \pi_j w_j)$ is a probability mass function over $\{0, \ldots, k\}$.

A detailed proof is provided in Appendix A.

A natural question to ask is whether BSVI’s $q_{\text{air}}$ is closer to the posterior than $q_k$ in expectation. To assist in this analysis, we first characterize a particular instance of the Generalized IWAE bound when $(z_1, \ldots, z_k)$ are independent but non-identically distributed.

Theorem 2. When $q(z_{0:k}) = \prod_i q_i(z_i)$, the implicit distribution $q_{\text{air}}(z)$ admits the inequality

$$E_{q_{\text{air}}(z)} \ln \frac{p_\theta(x, z)}{q_{\text{air}}(z)} \geq E_{q(z_{0:k})} \ln \sum_{i=0}^{k} \pi_i w_i$$  \hspace{1cm} (20)

$$= E_{q(z_{0:k})} \ln \sum_{i=0}^{k} \pi_i \frac{p_\theta(x, z)}{q_i(z_i)}. $$  \hspace{1cm} (21)

Theorem 2 extends the analysis by [23] from the i.i.d. case (i.e. the standard IWAE bound) to the non-identical case (proof in Appendix A). It remains an open question whether the inequality holds for the non-independent case.

Since the BSVI objective employs dependent samples, it does not fulfill the conditions for Theorem 2. To address this issue, we propose a variant, BSVI with double-sampling (BSVI-DS), that breaks dependency by drawing two samples at each SVI step: $\hat{z}_i$ for computing the SVI gradient update and $z_i$ for computing the BSVI importance weight $w_i$. The BSVI-DS bound is thus

$$E_{q(\hat{z}_{<k} \mid x)} \left( E_{q(z_{0:k} \mid \hat{z}_{<k}, x)} \ln \sum_{i=0}^{k} \pi_i \frac{p_\theta(x, z)}{q_i(z_i | \hat{z}_{<k}, x)} \right),$$  \hspace{1cm} (22)

where $q(z_{0:k} \mid \hat{z}_{<k}, x) = \prod_i q(z_i | \hat{z}_{<k}, x)$ is a product of independent but non-identical distributions when conditioned on $(\hat{z}_{<k}, x)$. Double-sampling now allows us to make the following comparison.

Corollary 1. Let $q_k = q(z_k | \hat{z}_{<k}, x)$ denote the proposal distribution found by SVI. For any choice of
For all our experiments, we use the same architecture as [18] (where the decoder is a PixelCNN) and train with the AMSGrad optimizer [24]. For grayscale SVHN, we follow [25] and replaced [18]'s bernoulli observation model with a discretized logistic distribution model with a global scale parameter. Each model was trained for up to 200k steps with early-stopping based on validation set performance. For the Omniglot experiment, we followed the training procedure in [18] and annealed the KL term multiplier [2, 26] during the first 5000 iterations. We replicated all experiments four times and report the mean and standard deviation of all relevant metrics. For additional details, refer to Appendix D

6.2 Log-Likelihood Performance

For all models, we report the log-likelihood (as measured by BSVI-500). We additionally report the SVI-500 (ELBO*) bound along with its decomposition into rate (KL*) and distortion (Reconstruction*) components [27]. We highlight that KL* provides a fair comparison of the rate achieved by each model without concern of misrepresentation caused by the amortized inference suboptimality.

Omniglot. Table 1 shows that BSVI-SIR outperforms SVI on the test set log-likelihood. BSVI-SIR also makes greater usage of the latent space (as measured by the lower Reconstruction*). Interestingly, BSVI-SIR’s log-likelihoods are noticeably higher than its corresponding ELBO*, suggesting that BSVI-SIR has learned posterior distributions not easily approximated by the Gaussian variational family when trained on Omniglot.

SVHN. Table 2 shows that BSVI-SIR outperforms SVI on test set log-likelihood. We observe that both BSVI-SIR and SVI significantly outperform both VAE and IWAE on log-likelihood, ELBO*, and Reconstruction*, demonstrating the efficacy of iteratively refining the proposal distributions found by amortized inference model during training.

FashionMNIST. Table 3 similarly show that BSVI-SIR outperforms SVI on test set log-likelihood. Here, BSVI achieves significantly better Reconstruction* as well as achieving higher ELBO* compared to VAE, IWAE, and SVI.

In Tables 4 to 6 (Appendix B), we also observe that the use of double sampling and buffer weight optimization does not make an appreciable difference than their appropriate counterparts, demonstrating the efficacy of BSVI even when the samples $(z_{0:k})$ are statistically dependent and the buffer weight is simply uniform.
Table 1: Test set performance on the Omniglot dataset. Note that \( k = 9 \) and \( k' = 10 \) (see Section 6.1). We approximate the log-likelihood with BSVI-500 bound (Appendix C). We additionally report the SVI-500 bound (denoted ELBO*) along with its KL and reconstruction decomposition.

6.3 Stochastic Gradient as Regularizer

![Training](image1)

![Validation](image2)

Figure 4: Performance comparison between BSVI and BSVI-SIR on training (top) and validation (bottom) sets for Omniglot. Although BSVI achieves lower training loss, BSVI-SIR avoids overfitting and performs better on the test set.

Interestingly, Table 4 shows that BSVI-SIR can out-perform BSVI on the test set despite having a higher variance gradient. We show in Figure 4 that this is the result of BSVI overfitting the training set. The results demonstrate the regularizing effect of having noisier gradients and thus provide informative empirical evidence to the on-going discussion about the relationship between generalization and the gradient signal-to-noise ratio in variational autoencoders [28, 16].

6.4 Latent Space Visualization

![Image3](image3)

Figure 5: Visualization of images sampled from decoder trained using SVI (top) and BSVI-SIR (bottom). Each row represents a different \( z \) sampled from the prior. Conditioned on \( z \), 20 images \( x^{(1:20)} \sim p_{\theta}(x \mid z) \) are then sampled from the PixelCNN decoder.
Table 1 shows that the model learned by BSVI-SIR training has better Reconstruction* than SVI, indicating greater usage of the latent variable for encoding information about the input image. We provide a visualization of the difference in latent space usage in Figure 5. Here, we sample multiple images conditioned on a fixed z. Since BSVI encoded more information into z than SVI on the Omniglot dataset, we see that the conditional distribution $p_0(x \mid z)$ of the model learned by BSVI has lower entropy (i.e. less diverse) than SVI.

### 6.5 Analysis of Training Metrics

![Plots of metrics during BSVI-k training.](image)

(a) Difference between lower bounds achieved by $q_k$ (SVI-k) and $q_0$ (SVI-0) during training.

(b) Difference between the BSVI-k bound and SVI-k bound during training.

(c) Plot of the buffer weight average (defined as $E_{w(i)/i/k}$) during training when the buffer weight is optimized.

Figure 6: Plots of metrics during BSVI-k training, where $k = 9$. Since BSVI-k uses SVI-k as a subroutine, it is easy to check how the BSVI-k bound compares against the SVI-k and the amortized ELBO (SVI-0) bounds on a random mini-batch at every iteration during training.

Recall that the BSVI-k training procedure runs SVI-k as a subroutine, and therefore generates the trajectory of importance weights $(w_0, \ldots, w_k)$. Note that $\ln w_0$ and $\ln w_k$ are unbiased estimates of the ELBO achieved by the proposal distribution $q_0$ (SVI-0 bound) and $q_k$ (SVI-k bound) respectively. It is thus possible to monitor the health of the BSVI training procedure by checking whether the bounds adhere to the ordering

$$\text{BSVI-k} \geq \text{SVI-k} \geq \text{SVI-0} \quad (25)$$

in expectation. Figures 6a and 6b show that this is indeed the case. Since Omniglot was trained with KL-annealing [18], we see in Figure 6a that SVI plays a negligibly small role once the warm-up phase (first 5000 iterations) is over. In contrast, SVI plays an increasingly large role when training on the more complex SVHN and FashionMNIST datasets, demonstrating that the amortization gap is a significantly bigger issue in the generative modeling of SVHN and Fashion-MNIST. Figure 6b further shows that BSVI-k consistently achieves a better bound than SVI-k. When the buffer weight is also optimized, we see in Figure 6c that $\pi$ learns to upweight the later proposal distributions in $(q_0, \ldots, q_k)$, as measured by the buffer weight average $E_{w(i)/i/k}$. For SVHN, the significant improvement of SVI-k over SVI-0 results in $\pi$ being biased significantly toward the later proposal distributions. Interestingly, although Figure 6c suggests that the optimal buffer weight $\pi^*$ can differ significantly from naive uniform-weighting, we see from Tables 1 and 2 that buffer weight optimization has a negligible effect on the overall model performance.

### 7 Conclusion

In this paper, we proposed Buffered Stochastic Variational Inference (BSVI), a novel way to leverage the intermediate importance weights generated by stochastic variational inference. We showed that BSVI is effective at alleviating inference suboptimality and that training variational autoencoders with BSVI consistently outperforms its SVI counterpart, making BSVI an attractive and simple drop-in replacement for models that employ SVI. One promising line of future work is to extend the BSVI training procedure with end-to-end learning approaches in [18, 19]. Additionally, we showed that BSVI procedure is a valid lower bound and belongs to general class of importance-weighted (Generalized IWAE) bounds where the importance weights are statistically dependent. Thus, it would be of interest to study the implications of this bound for certain MCMC procedures such as Annealed Importance Sampling [20] and others.
