On Discriminative Learning of Prediction Uncertainty

Vojtech Franc 1  Daniel Prusa 1

Abstract

In classification with a reject option, the classifier is allowed in uncertain cases to abstain from prediction. The classical cost based model of an optimal classifier with a reject option requires the cost of rejection to be defined explicitly. An alternative bounded-improvement model, avoiding the notion of the reject cost, seeks for a classifier with a guaranteed selective risk and maximal cover. We prove that both models share the same class of optimal strategies, and we provide an explicit relation between the reject cost and the target risk being the parameters of the two models. An optimal rejection strategy for both models is based on thresholding the conditional risk defined by posterior probabilities which are usually unavailable. We propose a discriminative algorithm learning an uncertainty function which preserves ordering of the input space induced by the conditional risk, and hence can be used to construct optimal rejection strategies.

1. Introduction

In classification with a reject option the classifier is allowed in uncertain cases to abstain from prediction. This setting is essential e.g. in medical diagnosis, safety critical systems and many other applications. The cost-based model of an optimal classification strategy with the reject option was proposed by Chow in his pioneering work (Chow, 1970). The goal is to minimize the expected loss equal to the cost of misclassification, if the classifier predicts, and to the reject cost, if the classifier abstains from prediction. The well known Bayes-optimal strategy rejects to predict whenever the conditional risk exceeds the reject cost. Computation of the conditional risk requires the class posterior probabilities which are usually unavailable. A common solution is the plug-in rule obtained after replacing the posterior probabilities by their estimates. A quality of the plug-in rule heavily depends on the estimated probabilities (Fumera et al., 2000; Herbei & Wegkamp, 2006). Discriminative methods instead learn the reject option classification strategy directly without the probability estimation, e.g. (Bartlett & Wegkamp, 2008; Ramaswamy & Agarwal, 2016). Many works assume that the uncertainty measure is known, e.g. obtained from responses of trained Neural Network (LeCun et al., 1990), and the task is to find only the rejection thresholds (Tortorella, 2000; Kummert et al., 2016; Fischer et al., 2016). Most existing methods, including this paper, account for aleatoric uncertainty only, while literature dealing with the epistemic uncertainty is scarce (Wang et al., 2017).

The cost-based model requires the reject cost to be defined explicitly which is difficult in some applications like e.g. medical diagnosis. An alternative bounded-improvement model proposed by (Pietraszek, 2005) avoids explicit definition of the reject cost. The rejection strategy is evaluated by two antagonistic quantities: i) the selective risk defined as the expected misclassification cost on the non-reject region and ii) the coverage corresponding to the probability mass of the non-reject region. An optimal strategy for the bounded-improvement model maximizes the coverage under the condition that the selective risk does not exceed a specified target value. In contrast to the cost-based model, it has not been formally shown what is the optimal class of strategies when the underlying model is known. The solution was proposed only for special instances of the task. (Pietraszek, 2005) proposed a method based on ROC analysis applicable when a score proportional to posterior probabilities is known and the task is to find only the optimal thresholds. (El-Yaniv & Wiener, 2010) proposed an algorithm learning the optimal strategy in the noise-free setting, i.e. when a perfect strategy with zero selective risk exists. (Geifman & El-Yaniv, 2017) shows how to equip a trained classifier with a reject option provided an uncertainty measure is known and the task is to find a rejection threshold optimal under the bounded-improvement model.

This paper describes three contributions:

1) We provide necessary and sufficient conditions for an optimal strategy of the bounded-improvement model when the underlying distribution is known. We show that an optimal
rejection strategy can be constructed based on thresholding
the class conditional risk, which corresponds to the optimal
strategy of the cost-based model. We show that in contrast to
the cost-based model, the rejection strategy cannot be arbi-
trary at the boundary cases. We provide an explicit relation
between the parameters of the two rejection models.

2) We propose a novel loss which evaluates the quality
of an uncertainty function associated to a given classifier.
We prove that any minimizer of an expectation of the loss
is a function which preserves ordering of the input space
induced by the true conditional risk. Hence, any minimizer
of the loss can be used to construct a strategy optimal for
cost-based and/or bounded-improvement model.

3) We propose a discriminative algorithm which for a given
classifier learns an uncertainty function by minimizing a
convex surrogate of the proposed loss. We show experi-
tently that the learned rejection strategies outperform plug-in
rules constructed from logistic-regression model and rules
based on distance to the SVM decision boundary.

To our knowledge we are the first to propose a discrimina-
tive method learning an uncertainty function with a clear
connection to the conditional risk being the key quantity
for constructing the optimal reject-option strategies. Our
method is potentially most useful when modeling the poste-
rior distribution of the nonlinear cost-based and/or bounded-improvement model.

The paper organization: Section 2 characterizes optimal
strategies of the bounded-improvement rejection model and
relation to the cost-based model. Section 3 proposes an algo-
ithm learning uncertainty function optimal for both models.
Related works are discussed in Section 4, experiments are
presented in Section 5 and a summary is given in Section 6.
Proofs are referred to a supplementary material.

2. Equivalence of Cost-based and
Bounded-improvement Rejection Models

Let \( \mathcal{X} \) be a set of input observations and \( \mathcal{Y} \) a finite set of
labels. Let us assume that inputs and labels are generated by
a random process with p.d.f. \( p(x, y) \) defined over \( \mathcal{X} \times \mathcal{Y} \). A
goal in the non-reject setting is to find a classifier \( h : \mathcal{X} \to \mathcal{Y} \) with a small expected risk

\[
R(h) = \int_{\mathcal{X}} \sum_{y \in \mathcal{Y}} p(x, y) \ell(y, h(x)) \, dx,
\]

where \( \ell : \mathcal{Y} \times \mathcal{Y} \to \mathbb{R}_+ \) is a loss penalizing the predictions.

The expected risk can be reduced by abstaining from pre-
diction in uncertain cases. To this end, we use a selective
classifier \(^1\) \( (h, c) \) composed of a classifier \( h : \mathcal{X} \to \mathcal{Y} \) and
a selection function \( c : \mathcal{X} \to [0, 1] \). When applying the

\[
(h, c)(x) = \begin{cases} 
  h(x) & \text{with probability } c(x), \\
  \text{reject} & \text{with probability } 1 - c(x).
\end{cases}
\]

In the sequel we introduce two models of an optimal selec-

tive classifier, the cost-based and the bounded-improvement
model, and we characterize their optimal strategies provided
the underlying model \( p(x, y) \) is known. While the solution
of the former model is well known the latter is novel.

**Cost-based model** seeks for a selective classifier
\( (h_B, c_B) \) which for a given reject cost \( \varepsilon > 0 \) minimizes

\[
R_B(h, c) = \int_{\mathcal{X}} \sum_{y \in \mathcal{Y}} p(x, y) \left( \ell(y, h(x)) c(x) + (1 - c(x)) \varepsilon \right) \, dx.
\]

The well-known optimal strategy (i.e. the Bayes classifier)
reads

\[
h_B(x) = \arg\min_{\hat{y} \in \mathcal{Y}} \sum_{y \in \mathcal{Y}} p(y | x) \ell(y, \hat{y}) \tag{1}
\]

\[
c_B(x) = \begin{cases} 
  1 & \text{if } r^*(x) < \varepsilon, \\
  \tau & \text{if } r^*(x) = \varepsilon, \\
  0 & \text{if } r^*(x) > \varepsilon,
\end{cases}
\]

where \( r^*(x) = \min_{\hat{y} \in \mathcal{Y}} \sum_{y \in \mathcal{Y}} p(y | x) \ell(y, \hat{y}) \) is the mini-
mal class conditional risk associated to the input \( x \), and \( \tau \)
is any number from the interval \([0, 1]\). Hence there is an in-
finite number of optimal selection functions parameterized
by \( \tau \) which yield the same risk \( R_B(h, c) \).

**Bounded-improvement model** characterizes the selec-
tive classifier by two antagonistic quantities: i) the

\[
\phi(c) = \int_{\mathcal{X}} p(x) c(x) \, dx
\]

corresponding to the probability mass of the non-reject re-

dion and ii) the selective risk

\[
R_S(h, c) = \int_{\mathcal{X}} \sum_{y \in \mathcal{Y}} p(x, y) \ell(y, h(x)) c(x) \, dx
\]

defined for non-zero \( \phi(c) \) as the expected classification loss
on the non-reject region \( \mathcal{X}_{c(x) > 0} \). Given a target risk

decomposition \( (h, c)(x) = h'(x) \), and the terminology selective
classifier from (El-Yaniv & Wiener, 2010) as it simplifies notation.

\(^1\)The classifier with a reject option is more frequently denoted
by a single function \( h' : \mathcal{X} \to \mathcal{Y} \cup \{\text{reject}\} \). Instead, we use the
where \( \lambda > 0 \), the bounded-improvement model defines the optimal selective classifier \((h_S, c_S)\) as a solution to the problem

\[
\max_{h, c} \phi(c) \quad \text{s.t.} \quad R_S(h, c) \leq \lambda, \tag{3}
\]

where we assume that both maximizers exist.

**Theorem 1** Let \((h, c)\) be an optimal solution to (3). Then, \((h_B, c)\), where \(h_B\) is the optimal Bayes classifier (1), is also optimal to (3).

According to Theorem 1 the Bayes classifier \(h_B\) is also optimal for the risk-coverage task (3) which is not surprising. Note the Bayes classifier is not a unique solution to (3) because the predictions on the reject region \(X_r(x) = 0\) do not count to the selective risk and hence they can be arbitrary.

Theorem 1 allows to solve the bounded-improvement task (3) in two consecutive steps: First, set \(h\) to be the Bayes classifier \(h_B\) or to its best approximation, e.g. learned by a discriminative method of choice. Second, when \(h\) is fixed, the optimal selection function \(c^*\) is obtained by solving the task (3) only w.r.t \(c\) which boils down to

\[
\max_{c \in [0, 1]} \int_X p(x) c(x) dx \quad \text{s.t.} \quad \int_X p(x) c(x) \tau(x) dx \leq 0 \tag{4}
\]

where \(\tau(x) = r(x) - \lambda\) measures how much the conditional risk of the prediction \(h(x)\), defined as

\[
r(x) = \sum_{y \in Y} p(y \mid x) \ell(y, h(x)), \tag{5}
\]

exceeds the target risk \(\lambda\). It is seen that for \(h = h_B\) solving (4) yields \(c^*\) which is a solution to the task (3), i.e. \(c^* = c_S\). Indeed, using the definition of \(R_S(h, c)\) we can rewrite the constraint of the task (3) as

\[
\int_X p(x) \sum_{y \in Y} p(y \mid x) \ell(y, h(x)) c(x) dx \leq \lambda \int_X p(x) c(x) dx
\]

which after a simple rearrangement becomes the constraint of the task (4), and objectives of both tasks are the same.

**Theorem 2** A selection function \(c^* : X \to [0, 1]\) is an optimal solution to (4) if and only if it holds

\[
\int_{X_r(x) < b} p(x) c^*(x) dx = \int_{X_r(x) < b} p(x) dx, \tag{6}
\]

\[
\int_{X_r(x) = b} p(x) c^*(x) dx = \begin{cases} -\frac{p(X_r(x) < b)}{b} & \text{if } b > 0, \\ \int_{X_r(x) = b} p(x) dx & \text{if } b = 0, \end{cases} \tag{7}
\]

\[
\int_{X_r(x) > b} p(x) c^*(x) dx = 0, \tag{8}
\]

where \(\rho(X') = \int_X p(x) \tau(x) dx\) is the expectation of \(\tau(x)\) restricted to inputs in \(X\), and

\[
b = \sup \{ a \mid \rho(X_r(x) \leq a) \leq 0 \} \geq 0. \tag{9}
\]

Theorem 2 defines behaviour of optimal selection function on the partition of the input space \(X\) into three regions \(X_{r(x) < b}, X_{r(x) = b}\) and \(X_{r(x) > b}\). The condition (6) says that the conditional expectation \(E_{r(x) < b} [c^*(x) | r(x) < b]\) is zero, which is satisfied if for \(r(x) < b\) we use \(c^*(x) = 1\). Or equivalently, by using the identity \(r(x) = r(x) - \lambda\), we set \(c^*(x) = 1\) whenever \(r(x) < \gamma\) with the threshold \(\gamma = b + \lambda\). Analogically, setting \(c^*(x) = 0\) for \(r(x) > \gamma\) satisfies the condition (8). Finally, if we opt for a constant selecting function \(c^*(x) = \tau\) in the boundary region \(X_{r(x) = b}\), then the condition (7) implies \(\tau = -\frac{p(X_r(x) < b)}{b - \rho_0}\) if \(b > 0\), where \(\rho_0 = \int_{X_r(x) = b} p(x) dx\), and \(\tau = 1\) if \(b = 0\). Using \(X_{r(x) < b} = X_{r(x) < \gamma}\) and \(b = \rho_0 = \rho(X_{r(x) = b}), \rho(X_{r(x) = \gamma})\), we derive

\[
\tau = \begin{cases} 1 & \text{if } \rho(X_{r(x) = \gamma}) = 0, \\ \frac{-p(X_r(x) < \gamma)}{p(X_{r(x) = \gamma})} & \text{if } \rho(X_{r(x) = \gamma}) > 0. \end{cases} \tag{10}
\]

**Corollary 1** Let \(r : X \to \mathbb{R}\) be the conditional risk (5), \(\tau\) the acceptance probability given by (10) and \(\gamma = b + \lambda\) the rejection threshold given by the target-risk \(\lambda\) and \(b\) computed by (9). Then the selection function

\[
c^*(x) = \begin{cases} 1 & \text{if } r(x) < \gamma, \\ \tau & \text{if } r(x) = \gamma, \\ 0 & \text{if } r(x) < \gamma, \end{cases} \tag{11}
\]

satisfies the optimality condition of Theorem 2.

It is seen that (11) coincides with the Bayes-optimal selection function (2) of the cost-based model. In case of the cost-based model, the threshold \(\gamma\) corresponds to the reject cost \(c\) while the acceptance probability \(\tau\) can be arbitrarily without affecting the risk \(R_B(h, c)\). In contrast, the optimal threshold \(\gamma = b + \lambda\) of the bounded-improvement model is defined implicitly by choosing the target risk \(\lambda\). In addition, the acceptance probability \(\tau\) for the boundary cases cannot be arbitrary in general. In practice, however, the impact of \(\tau\) is negligible because \(\rho_0\) is usually small or even zero as can be expect for continuous \(p(x)\) when the boundary region \(X_{r(x) = \gamma}\) has probability measure zero. On the other hand, setting the threshold \(\gamma\) is crucial. Fortunately, (Geifman & El-Yaniv, 2017) shows how to find \(\gamma\) from a finite training set such that it is optimal solution of the bounded-improvement model in PAC sense. The remaining issue is thus the conditional risk \(r(x)\) because its computation requires the posterior probabilities \(p(y \mid x)\). A common solution is the plug-in rule obtained after replacing \(p(y \mid x)\) in (5) by \(\widehat{p}(y \mid x)\) estimated from examples. In the next section, we propose an alternative approach which completely avoids the probability estimation.
3. Discriminative Learning of Uncertainty

Assume a classifier \( h: \mathcal{X} \to \mathcal{Y} \) has been fixed and we want to endow it with a selection function \( c: \mathcal{X} \to [0, 1] \). We have shown that regardless the rejection model, the optimal selection function is based on thresholding the conditional risk \( r(x) \) defined by \((5)\). Hence, it is clear that \( r(x) \) can be replaced by any uncertainty function \( s: \mathcal{X} \to \mathbb{R} \) which preserves ordering induced by the conditional risk \( r(x) \). In this section, we show how to learn such uncertainty functions from examples.

3.1. Order Enforcing Loss Function

Let \( T_n = \{(x_i, y_i) \in \mathcal{X} \times \mathcal{Y} | i = 1, ..., n\} \) be a set of inputs and labels generated from \( n \) i.i.d. random variables with distribution \( p(x, y) \). We define a loss function \( \Delta: \mathbb{R}^n \times \mathcal{X}^n \times \mathcal{Y}^m \to \mathbb{R}_+ \) as

\[
\Delta(s, T_n) = \frac{1}{n^2} \sum_{i=1}^{n} \sum_{j=1}^{n} \ell(y_i, h(x_i)) [s(x_i) \leq s(x_j)],
\]

which has the following interpretation. Let us order the examples \( T_n \) according to \( s(x) \) so that \( s(x_{\pi(1)}) \leq s(x_{\pi(2)}) \leq \cdots \leq s(x_{\pi(n)}) \), where \( \pi: \{1, ..., n\} \to \{1, ..., n\} \) is the permutation defining the order. Let \( \hat{R}(i, s) = \frac{1}{n} \sum_{j=1}^{n} \ell(y_j, h(x_j)) [s(x_j) \leq s(x_{\pi(j)})] \) be the empirical risk of the classifier \( h(x) \) computed on the examples with uncertainty not higher than \( s(x) \) in the \( i \)-th example. Then, the loss \( \Delta(s, T_n) \) can be seen as the area under the curve \( C = \{(\hat{R}(i, s), \frac{i}{n}) | i = 1, ..., n\} \). The curve \( C \) summarizes performance of the selective classifier on \( T_n \) when it rejects to predict based on thresholding the uncertainty \( s(x) \). It is intuitively clear that the area is minimized by such \( s(x) \) which orders the examples as if they were ordered according to the loss \( \ell(y_j, h(x_j)) \). Hence, by minimizing the expectation of \( \Delta(s, T_n) \) we should get a function preserving the ordering induced by the conditional risk. In the sequel we will use the intuition by theorems.

Let us define the expectation of the loss \( \Delta(s, T_n) \) as

\[
E(s) = \int_{\mathcal{X}^n} \sum_{y \in \mathcal{Y}^n} \prod_{i=1}^{n} p(x_i, y_i) \Delta(s, T_n) dx
\]

\[
= \frac{1}{n^2} \int_{\mathcal{X}^n} \prod_{i=1}^{n} p(x_i) \sum_{i=1}^{n} \sum_{j=1}^{n} r(x_i) [s(x_i) \leq s(x_j)] dx
\]

\[
= \frac{1}{n^2} \sum_{i=1}^{n} \sum_{j=1}^{n} \int_{\mathcal{X}} p(x) p(z) r(x) [s(x) \leq s(z)] dz dx
\]

\[
= \int_{\mathcal{X}} p(x) r(x) \left( \int_{\mathcal{X}} p(z) [s(x) \leq s(z)] dz \right) dx,
\]

its minimizers are described by the following theorem.

**Theorem 3** A function \( s^*: \mathcal{X} \to \mathbb{R} \) is an optimal solution to \( \min_{s: \mathcal{X} \to \mathbb{R}} E(s) \) if and only if

\[
\int_{\mathcal{X}} \int_{s^*(z) = s^*(x)} \max\{r(x), r(z)\} p(x) p(z) dz dx = 0, \quad \text{and} \quad \int_{\mathcal{X}} \int_{r(z) < r(x)} (r(x) - r(z)) p(x) p(z) dz dx = 0.
\]

The conditions (13) and (14) imply that the conditional expectations \( \mathbb{E}_{x, z \sim p(x)} \max\{r(x), r(z)\} | z \neq x \wedge s^*(x) = s^*(z) \) and \( \mathbb{E}_{x, z \sim p(x)} r(x) - r(z) | r(z) < r(x) \wedge s^*(x) > s^*(z) \) are both zero. If combined it further implies that a subset of input space \( \mathcal{X}' = \{z \in \mathcal{X} \times \mathcal{X} | r(z) < r(x) \wedge s^*(z) > s^*(x)\} \) on which the order is violated has probability measure 0. In other words the optimal \( s^*(x) \) preserves the ordering induced by \( r(x) \) almost surely.

**Corollary 2** Any function \( s: \mathcal{X} \to \mathbb{R} \) fulfilling

\[
\forall (x, x') \in \mathcal{X} \times \mathcal{X}: x \neq x' \Rightarrow s(x) \neq s(x'), \quad \text{and} \quad \forall (x, x') \in \mathcal{X} \times \mathcal{X}: r(x) < r(x') \Rightarrow s(x) < s(x')
\]

satisfies the optimality conditions of Theorem 3.

Corollary 2 suggests how to construct the optimal \( s^*(x) \) if we know the conditional risk \( r(x) \). More importantly, the following corollary states that the optimal \( s^*(x) \) can be used instead of \( r(x) \) to construct the optimal selection function.

**Corollary 3** Let \( s^* \in \text{argmin}_{s: \mathcal{X} \to \mathbb{R}} E(s) \). The selection function \( c^*: \mathcal{X} \to [0, 1] \) defined by

\[
c^*(x) = \begin{cases} 1 & \text{if } s^*(x) < \gamma, \\ \tau & \text{if } s^*(x) = \gamma, \\ 0 & \text{if } s^*(x) > \gamma, \end{cases}
\]

where \( \gamma = \sup \{a | \rho(X_{s^*(x)\leq a}) \leq 0\} \),

\[
\text{and } \tau = \begin{cases} -\rho(X_{s^*(x)\leq a})/\rho(X_{s^*(x)\gamma}) & \text{if } \rho(X_{s^*(x)\gamma}) > 0, \\ 0 & \text{otherwise.} \end{cases}
\]

fulfills conditions (6), (7) and (8) of Theorem 2, therefore it is an optimal solution to (4).

3.2. Algorithm

The expectation \( E(s) \) cannot be minimized directly because \( p(x, y) \) is unknown and the loss \( \Delta(s, T_n) \) is hard to optimize due to the step function \([0 \leq t] \) in its definition. We have that \( \int_{\mathcal{X}} \int_{s^*(x) = s^*(z)} f(x, z) dz dx \) stands for \( \int_{\mathcal{X}} \int_{s^*(x) = s^*(z)} f(x, z) dz dx \) where \( \mathcal{X}' = \{z \in \mathcal{X} | z \neq x \wedge s^*(z) = s^*(x)\} \), etc.
describe two standard techniques to minimize $E(s)$ approximately given a training set $\mathcal{T}_m = \{(x_i, y_i) \in \mathcal{X} \times \mathcal{Y} \mid i = 1, \ldots, m\}$ drawn i.i.d. from $p(x, y)$. We assume that uncertainty function $s_\theta : \mathcal{X} \rightarrow \mathbb{R}$ is known up to parameters $\theta \in \mathbb{R}^n$ which need to be learned from $\mathcal{T}_m$.

Stochastic Gradient Approximation Starting from initial $\theta_0 \in \mathbb{R}^n$, the new values are computed in iterative fashion by $\theta_{t+1} = \theta_t + k_t g_t$, where $k_t$ is an appropriate learning rate and $g_t$ is a sub-gradient evaluated at $\theta_t$ of the proxy-loss

$$\hat{\Delta}(\theta, \mathcal{T}_n) = \frac{1}{n^2} \sum_{i=1}^n \sum_{j=1}^n \ell(y_i, h(x_i)) \omega(s_\theta(x_j) - s_\theta(x_i))$$

where $\omega(t) = \max\{0, 1 + t\}$ is a convex upper-bound of $[0 \leq t]$ used in definition of the original loss $\Delta(s_\theta, \mathcal{T}_n)$. The set $\mathcal{T}_n$ denotes a mini-batch selected randomly from $\mathcal{T}_m$. It is seen that the true objective $E(s_\theta)$ is upper bounded by the expectation (w.r.t. randomly generated $\mathcal{T}_n$) of $\hat{\Delta}(\theta, \mathcal{T}_n)$ which we use as our proxy, and which can be optimized by SGD (Kushner & Yin, 2003) or similar algorithms.

Regularized Empirical Risk Approximation We approximate $E(s)$ by

$$F(\theta, \mathcal{T}_m) = \frac{C}{2} \|\theta\|^2 + \frac{1}{P} \sum_{k=1}^P \hat{\Delta}(\theta, \mathcal{T}^k)$$

where $\mathcal{T}^1 \cup \mathcal{T}^2 \cup \cdots \cup \mathcal{T}^P$ is randomly generated partition of the training set $\mathcal{T}_m$ into $P$ approximately equally sized batches, and $C > 0$ is a chosen regularization constant. It is seen that the expectation (w.r.t. randomly generated $\mathcal{T}_n$) of $F(\theta, \mathcal{T}_n)$ upper bounds $E(s)$. The objective $F(\theta, \mathcal{T}_n)$ is convex in $\theta$ for uncertainty functions $s_\theta(x) = \langle \theta, \psi(x) \rangle$ linear in $\theta$ and then any convex solver can be used.

4. Related Works

The cost-based rejection model was proposed in (Chow, 1970) who also provides the optimal strategy in case the distribution is known, analyzes the error-reject trade-off, and proves basic properties of the error-rate and the reject-rate, e.g. that both functions are monotone w.r.t. the reject cost. The original paper considers the risk with 0/1-loss only. The model with arbitrary prediction costs was analyzed e.g. in (Tortorella, 2000; Schlesinger & Hlavič, 2002).

The bounded-improvement model was proposed in (Pietraszek, 2005). He assumed that the classifier score proportional to the posterior probabilities is known and the task is to find only the optimal thresholds, which is done numerically based on ROC analysis. The original formulation assumes two classes and 0/1-loss. In our paper we consider a straightforward generalization of the bounded-improvement model, defined by task (3), which allows arbitrary number of classes, arbitrary loss and puts no constraint on the class of optimal strategies. We show how to construct the optimal strategy provided the underlying distribution $p(x, y)$ is known.

Learning of a selective classifier optimal for the bounded-improvement model was discussed in (El-Yaniv & Wiener, 2010). Their method requires a noisy-free scenario, i.e. there must exist a selective classifier with $R_S(h, c) = 0$. They also provide a characterization of the lower and upper bound of the risk-coverage curves in PAC setting. (Geifman & El-Yaniv, 2017) proposed a method to find a threshold optimal in PAC sense provided the uncertainty function $s(x)$ is known, which in their work is constructed from an output of a trained Neural Network. We complement their work by a method learning the uncertainty function $s(x)$.

A common approach to construct a rejection strategy is based on plug-in conditional risk $\hat{r}(x)$ obtained after replacing $p(y \mid x)$ in (5) by their estimate $\hat{p}(y \mid x)$. (Fumera et al., 2000) shows that the plug-in Bayes-optimal strategy is not optimal if the estimates $\hat{p}(y \mid x)$ are affected by errors, in which case they propose to use class-related thresholds instead of a single global threshold. Other methods trying to improve the plug-in strategy by tuning multiple thresholds were proposed in (Kummert et al., 2016; Fischer et al., 2016). The statistically consistency of the plug-in reject rules is discussed in (Herbei & Wegkamp, 2006). We use the plug-in rule on top of logistic-regression model (McCullagh & Nelder, 1989) as a baseline in our experiments.

Most prediction models come with at least an ordinal measure of uncertainty which can be used to construct the reject strategies. E.g. (LeCun et al., 1990) proposed a reject strategy for a Neural Network classifier based on thresholding either i) the output of the maximally activated unit of the last layer or ii) a difference between the maximal and runner upper output units. In case of Support Vector Machine classifiers (Vapnik, 1998) the trained linear score, proportional to the distance between the input and the decision hyperplane, is often used as the uncertainty measure (Fumera & Roli, 2002). We consider this approach as a baseline in our experiments. Other solutions involve fitting a probabilistic model to the SVM outputs (Platt, 2000; Wu et al., 2004).

5. Experiments

We experimented with two methods to learn the classifier $h(x)$ and two baselines to compute the uncertainty measure: i) Logistic-Regression estimating $\hat{p}(y \mid x)$ so that the plug-in Bayes classifier and the conditional risk can be computed, ii) the SVMs, representing discriminative methods without probabilistic output, in which case the classification
where \( \psi(x) = x \) are unknown parameters. We experimented with three different feature maps: i) linear features \( \psi(x) = x \), ii) quadratic features \( \psi(x) = (x_i \cdot x_j | (i, j) \in \{1, \ldots, d\}^2 \land j \leq i \) and iii) features extracted by multi-layer perceptron trained from examples. For linear and quadratic features, \( \psi \) is fixed and the unknown parameters \( \theta = W \) were learned by minimizing the convex objective function (21) using the Bundle Method for Risk Minimization (Choon et al., 2010). The number of batches was \( P = 5 \), and the regularization constant \( C \) was selected from \{1, 10, 100, 1000\} based on the proposed loss (12) evaluated on the validation set. Finally, we used MLP with 1, 5, or 10 layers (the optimal number was selected based on the validation set) each having the same number of neurons as the input dimension \( d \). The ReLU was used as the transfer function. The unknown parameters \( \theta = (\psi, W) \) comprised of the linear filters of fully-connected layers \( \psi \) and parameters \( W \) of the rule (22) put as the last layer. The parameters \( \theta \) were learned by ADAM (Kingma & Ba, 2015) optimizing the convex loss function (20). To speed up convergence, we used the batch-normalization (Ioffe & C. Szegedy, 2015) placed after each fully-connected layer.

### 5.1. Datasets

We selected 10 classification problems from UCI repository (Dua & Taniskidou, 2017) and libSVM datasets (Chang & C.J. Lin, 2011). The datasets are summarized in Table 1. We chose the datasets with sufficiently large number of examples, as we need to learn both the classifier and the uncertainty, and with a moderate input dimension \( d \) because of using \( q = d(d + 1)/2 \) explicitly computed quadratic features. Each dataset was randomly split 5 times into 5 subsets, Tm1/Val1/Tm2/Val2/Tst, in ratio 30/10/30/10/20 (up to COVTYPE with ratio 28/20/20/20/30). The subsets Tm1/Val1 and Tm2/Val2 were used for learning and model selection of the classifier and the uncertainty function, respectively. All features were normalized to have zero mean and unit variance. The normalization coefficients were estimated using only the Tm1 and Tm2 subsets, respectively. The Tst subset was used solely to compute the test metrics.

### 5.2. Evaluation Protocol

Selective classifiers are evaluated based on Risk-Coverage curve \( \{ (\hat{R}_S(i, s), \frac{\pi}{n}) | i = 1, \ldots, n \} \) where \( \hat{R}_S(i, s) \) is an estimate of \( R_S(h, c) \) computed on test examples by

\[
\hat{R}_S(i, s) = \frac{1}{\pi} \sum_{j=1}^{\pi} \ell(y_{\pi(j)}, h(x_{\pi(j)})),
\]

\( \pi(j) \) is the permutation obtained by sorting the examples according to \( s(x) \) in ascending order. We describe the performance by the selective risk at coverage 90%, defined as \( R_{@90} = \hat{R}_S(i, s) \) where \( i = \text{round}(0.9n) \), and by the Area Under risk-coverage Curve

The Tst subset was used solely to compute the test metrics.
We proved that the cost-based and bounded-improvement loss function whose minimizer is an uncertainty function which preserves ordering induced by the conditional risk, and hence can be used to construct an optimal reject strategy for both models. We experimentally showed that Logistic-Regression and SVM-based selective classifiers with uncertainty function learned by minimizing a convex-surrogate of the proposed loss outperform commonly used reject rules.

Open questions involve e.g. i) analysis of the statistical consistency of the proposed convex proxy-loss (20) and ii) investigating the possibility to simultaneously learn both the uncertainty and the prediction rule instead of using the data demanding two-stage approach.

Table 2. Area Under risk-coverage Curve (AUC), selective risk at coverage 90% and 100% are shown for selective classifiers built from the non-rejection LR or SVM models. The baseline selective function for LR model uses the plug-in conditional risk and the max-score for SVM. Below each baseline we report results for the selective classifiers with learned confidence measure. We report results only for model with the best features (L)inear, (Q)adratic and (M)ulti-layer perceptron selected based on the validation set.
Figure 1. The risk-coverage curves for different selective classifiers evaluated on 10 datasets. X-axis is the coverage and y-axis is the selective risk corresponding to the misclassification error on the non-reject area. The classifier is either LR (left sub-figure) or SVM (right sub-figure). The curves for baseline selective functions shown in black correspond to the plug-in conditional risk for LR and to the max-score for SVM. Colored curves correspond to selective functions learned by the proposed algorithm on top of linear features (red), quadratic features (green) and features extracted by multi-layer perceptron (blue).
On Discriminative Learning of Prediction Uncertainty
