Abstract

We consider the problem of convex function chasing with black-box advice, where an online decision-maker aims to minimize the total cost of making and switching between decisions in a normed vector space, aided by black-box advice such as the decisions of a machine-learned algorithm. The decision-maker seeks cost comparable to the advice when it performs well, known as consistency, while also ensuring worst-case robustness even when the advice is adversarial. We first consider the common paradigm of algorithms that switch between the decisions of the advice and a competitive algorithm, showing that no algorithm in this class can improve upon $3$-consistency while staying robust. We then propose two novel algorithms that bypass this limitation by exploiting the problem's convexity. The first, INTERP, achieves $(\sqrt{2} + \epsilon)$-consistency and $O(C^2 \epsilon^2)$-robustness for any $\epsilon > 0$, where $C$ is the competitive ratio of an algorithm for convex function chasing or a subclass thereof. The second, BDINTERP, achieves $(1 + \epsilon)$-consistency and $O(CD \epsilon)$-robustness when the problem has bounded diameter $D$. Further, we show that BDINTERP achieves near-optimal consistency-robustness trade-off for the special case where cost functions are $\alpha$-polyhedral.

Keywords: Convex body chasing, online optimization, learning-augmented algorithms

1. Introduction

We study the problem of convex function chasing (CFC), in which a player chooses decisions $x_t$ online from a normed vector space $\mathcal{X} = (X, \| \cdot \|)$ in order to minimize the total cost $\sum_{t=1}^{T} f_t(x_t) + \|x_t - x_{t-1}\|$, where each $f_t$ is a convex “hitting” cost function that is revealed prior to the player’s selection of $x_t$, and the term $\|x_t - x_{t-1}\|$ penalizes changing decisions between rounds. A number of subclasses of CFC have been discussed in the literature, characterized by various restrictions on the class of cost functions $f_t$. Of particular note is the special case of convex body chasing (CBC), in which each cost function $f_t$ is the $\{0, \infty\}$ indicator of a convex set $K_t$, so that each decision $x_t$ must reside strictly within $K_t$. Algorithms for CFC and its special cases are judged on the basis of their competitive ratio, i.e., the worst-case ratio in cost between the algorithm and the hindsight optimal sequence of decisions (Definition 1).

Convex body chasing and function chasing were introduced by Friedman and Linial (1993) as continuous versions of several fundamental problems in online algorithms, including Metrical Task Systems (Borodin et al. (1992)) and the k-server problem (Koutsoupias and Papadimitriou (1995)). CFC has also been studied recently as the problem of “smoothed online convex optimization” (SOCO), introduced by Lin et al. (2012). The basic premise of CFC/SOCO, of choosing decisions online to optimize per-round costs with minimal movement between decisions, has seen wide application in a number of domains, including data center load-balancing (Lin et al. (2012)) and right-sizing (Lin et al. (2013); Albers and Quedenfeld (2018)), electric vehicle charging (Kim and Giannakis (2014)), and control (Goel and Wierman (2019); Li et al. (2021)).
In high-dimensional settings, the performance of algorithms for CBC and CFC can be arbitrarily poor: Friedman and Linial (1993) showed a $\sqrt{d}$ lower bound on the competitive ratio of any algorithm for CBC (and thus CFC) in $d$-dimensional Euclidean space, which Bubeck et al. (2019) extended to an $\Omega(\max\{\sqrt{d}, d^{1-\frac{1}{p}}\})$ lower bound in $\mathbb{R}^d$ with the $\ell^p$ norm. Prospects are poor even for subclasses of CFC with additional restrictions on the functions $f_t$. For instance, CFC with $\alpha$-polyhedral cost functions, i.e., where each $f_t$ has a unique minimizer away from which it grows with slope at least $\alpha > 0$, has been studied widely in the SOCO literature. State-of-the-art algorithms in this setting achieve competitive ratio $O(\alpha^{-1})$, which grows arbitrarily large in the $\alpha \to 0$ limit (Chen et al. (2018); Zhang et al. (2021)).

The modern tools of machine learning wield great promise for improving upon these pessimistic performance guarantees. That is, for practical applications, there is often large amounts of data recorded from past problem instances, enabling the training of machine learning models that can outperform traditional, conservative online algorithms. However, these machine-learned algorithms are “black boxes,” in the sense that they lack rigorous, worst-case performance guarantees. Such black-box algorithms might typically outperform robust online algorithms, but their lack of uncertainty quantification can lead to arbitrarily poor performance in the worse case, if they are deployed on held-out problem instances or under distribution shift.

Thus, a natural question arises: is it possible to develop algorithms that achieve both the worst-case guarantees of traditional online algorithms for CFC and the average-case performance of machine-learned algorithms or other sources of black-box “advice”?

These desiderata are naturally encoded in the notions of robustness and consistency introduced by Lykouris and Vassilvtsiuk (2018) in the context of competitive caching. In this framework, a consistent algorithm is one with a competitive ratio with respect to the black-box advice, implying that when the advice is accurate, the algorithm will perform well; on the other hand, a robust algorithm is one that has a finite competitive ratio, regardless of advice performance. Our goal is to develop algorithms with tunable robustness and consistency guarantees, so that a decision-maker can decide in advance the trade-off they wish to make between exploiting good advice performance and ensuring worst-case robustness in the case that advice performs poorly.

1.1. Contributions

We answer the question above by proposing novel algorithms with tunable robustness and consistency bounds for CFC and any subclass thereof. In particular, we reduce the problem of designing robust and consistent algorithms for CFC to the design of bicompetitive meta-algorithms (Definitions 4, 5), which are unified “recipes” for combining black-box advice with a robust algorithm in a manner that guarantees a competitive ratio with respect to both ingredients. These “recipes” are very general – they can be used to combine advice with any algorithm for any subclass of CFC to obtain a customized robustness and consistency guarantee for that subclass without explicit knowledge of the algorithm or advice design.

More specifically, our contributions are twofold. We first consider the class of “switching” algorithms, which switch between the decisions of the advice and a robust algorithm. This class of algorithms has received considerable attention in the literature on robustness and consistency, and in particular, all prior algorithms for CFC with black-box advice in dimension greater than one have been switching algorithms. We prove a fundamental limit on the robustness and consistency of any switching algorithm for CFC, showing that no switching algorithm for CFC can improve on...
3-consistency while obtaining finite robustness (Theorem 8). We give a switching meta-algorithm \textsc{Switch} (Appendix B.1, Algorithm 4) achieving this fundamental limit, obtaining \((3 + \mathcal{O}(\epsilon))\)-consistency and \(\mathcal{O}(\frac{C}{\epsilon^2})\)-robustness for any \(\epsilon > 0\), where \(C\) is the competitive ratio of any algorithm for CFC or a subclass thereof. We further show that the fundamental limit on switching algorithms can be broken in the special case of nested CBC, in which successive bodies are nested. In this setting, we provide an algorithm \textsc{NestedSwitch} (Algorithm 1) achieving \((1 + \epsilon)\)-consistency along with \(\mathcal{O}(\frac{\epsilon}{d})\)-robustness for nested CBC in \(d\) dimensions (Proposition 9).

Second, galvanized by the limitations of switching algorithms, we develop algorithms exploiting the convexity of the CFC problem to obtain improved robustness and consistency bounds. We propose a meta-algorithm \textsc{Interp} (Algorithm 2) that, given a \(C\)-competitive algorithm for a subclass of CFC, achieves \((\mu(X) + \epsilon)\)-consistency and \(\mathcal{O}(\frac{C}{\epsilon^2})\)-robustness for any desired \(\epsilon > 0\), where \(\mu(X)\) is a geometric constant depending on the structure of the normed space \(X\) that is \(\sqrt{2}\) in any Hilbert space and is strictly less than 3 in any \(\ell^p\) space, \(p \in (1, \infty)\) (Theorem 11). Moreover, under the additional assumption that the advice and the \(C\)-competitive algorithm are never farther apart than some distance \(D\), we give a meta-algorithm \textsc{BdInterp} (Algorithm 3) that achieves \((1 + \epsilon)\)-consistency and \(\mathcal{O}(\frac{C}{\epsilon D})\)-robustness (Theorem 12). In particular, \textsc{BdInterp} gives nearly-optimal consistency and robustness for the problem of CFC with \(\alpha\)-polyhedral hitting cost functions when \(D = O(1)\) in \(\alpha\).

A key feature of our results is their generality: our main results on bicompetitive meta-algorithms (Proposition 7, Theorems 11, 12) hold in vector spaces with any norm and arbitrary, even infinite, dimension. This enables application to problems where the decisions \(x_t\) are infinite-dimensional objects such as probability measures, which could arise in settings such as iterated games. Moreover, these meta-algorithms enable the design of customized robust and consistent algorithms for \textit{any} subclass of CFC, since they are agnostic to the specific algorithms used. We illustrate this by giving specific robustness and consistency results for the cases of CFC, CBC, and CFC restricted to \(\alpha\)-polyhedral hitting cost functions; we give further examples in Appendix F.

1.2. Related work

Our work contributes to the literatures on CBC, CFC, and SOCO as well as the emerging literature on online algorithms with black-box advice. We discuss each in turn below.

1.2.1. CBC, CFC, and SOCO

The problems of convex body chasing and function chasing were introduced by Friedman and Linial (1993), who gave a competitive algorithm for CBC in 2-dimensional Euclidean space. The problem in general dimension \(d\) has been largely settled in the last few years. In the setting where subsequent bodies are nested, Argue et al. (2019) gave an \(\mathcal{O}(d \log d)\)-competitive algorithm in any norm, and Bubeck et al. (2019) later gave an \(\mathcal{O}(\min\{d, \sqrt{d \log T}\})\)-competitive algorithm in the Euclidean setting that uses the geometric Steiner point of the convex bodies. Later, Argue et al. (2021) and Sellke (2020) concurrently obtained \(\mathcal{O}(d)\)-competitive algorithms for general CFC. The latter work builds upon the methods of Bubeck et al. (2019), developing a “functional” Steiner point algorithm that is \(d\)-competitive for CBC and \((d + 1)\)-competitive for CFC in any normed space, matching the lower bound of \(d\) in the \(\ell^\infty\) norm setting.

Several special cases of CFC/SOCO with restrictions on hitting cost structure have been studied in the literature to the end of obtaining “dimension-free” competitive ratios for these subclasses. Chen et al. (2018) obtained the first such bound for the subclass of CFC where hitting cost functions
Table 1: Competitive ratios for state-of-the-art algorithms for CFC, CBC, and $\alpha$CFC.

$f_t$ are $\alpha$-polyhedral, which we call $\alpha$CFC. The authors propose an algorithm, “Online Balanced Descent” (OBD), which achieves a competitive ratio $O\left(\frac{1}{\alpha}\right)$. This upper bound has been successively refined, with the most recent entry a simple greedy algorithm from Zhang et al. (2021) that achieves competitive ratio $\max\{1, \frac{2}{\alpha}\}$ in any normed vector space of arbitrary (even infinite) dimension by moving to the minimizer of each hitting cost function. The $O\left(\frac{1}{\alpha}\right)$ upper bound has been broken by Lin (2022) in the finite-dimensional Euclidean setting with an $O\left(\frac{1}{\alpha^{1/2}}\right)$-competitive algorithm, Greedy OBD, that is optimal within the class of memoryless, rotation- and scale-invariant algorithms. Another subclass of CFC that has received attention is that with $(\kappa, \gamma)$-well-centered hitting cost functions, which generalize well-conditioned functions. Argue et al. (2020) propose an algorithm achieving an $O\left(2^{\gamma/2}\kappa\right)$ competitive ratio for this subclass, and an improved algorithm achieving competitive ratio $O\left(\sqrt{\kappa}\right)$ for the particular class of $\kappa$-well-conditioned functions along with a nearly matching $\Omega\left(\kappa^{1/3}\right)$ lower bound. We summarize the state-of-the-art algorithms and competitive ratios that we refer to in our later results in Table 1, giving an extended version of the table in Appendix A, Table 2.

1.2.2. Online Algorithms with Black-Box Advice

The idea of using machine-learned, black-box advice to improve online algorithms was first proposed by Mahdian et al. (2012) to design algorithms for online ad allocation, load balancing, and facility location. Formal notions of robustness and consistency were later coined by Lykouris and Vassilvitskii (2018) in the context of designing learning-augmented algorithms for caching. The last few years have seen a surge in the application of the robustness and consistency paradigm in designing online algorithms augmented with black-box advice for a multitude of problems, for example ski rental and non-clairvoyant scheduling (Purohit et al. (2018); Wei and Zhang (2020)), energy generation scheduling (Lee et al. (2021)), bidding and bin-packing (Angelopoulos et al. (2020)), and Q-learning (Golowich and Moitra (2021)).

Closest to our work are the recent papers of Antoniadis et al. (2020) and Rutten et al. (2022). The former considers the problem of designing algorithms for metrical task systems (MTS) with black-box advice. MTS can be thought of as (non-convex) function chasing on general metric spaces, and hence their results also give robustness/consistency guarantees for CFC. They apply two classical results on combining $k$-server algorithms (Fiat et al. (1994); Baeza-Yates et al. (1993)) and on combining MTS algorithms via $k$-experts algorithms (Blum and Burch (1997); Freund and Schapire (1997)) to devise, in our parlance, bicompetitive meta-algorithms for MTS. In particular, their first algorithm switches between the advice and a $C$-competitive algorithm for MTS, and achieves $9$-consistency and $9C$-robustness. They also propose a randomized switching algorithm that, under
the assumption that the metric space has bounded diameter \( D \), obtains cost bounded in expectation by 
\[
\min\{ (1 + \epsilon) C_{\text{ADV}} + O\left(\frac{D}{\epsilon}\right), (1 + \epsilon) C_{\text{OPT}} + O\left(\frac{D}{\epsilon}\right) \}
\]
where \( C_{\text{ADV}} \) is the cost of the advice and \( C_{\text{OPT}} \) is the optimal cost. However, the large \( O\left(\frac{D}{\epsilon}\right) \) additive factors in their result preclude \((1 + \epsilon)\)-consistency, since when \( C_{\text{ADV}} = O(1) \), the consistency bound will be \( 1 + \epsilon + \Omega\left(\frac{D}{\epsilon}\right) \). This is to be expected, since as we show in Section 3, no deterministic switching algorithm can improve on 3-consistency while having finite robustness. Moreover, their results due not allow tuning robustness and consistency, i.e., neither algorithm allows trading-off robustness in order to obtain consistency arbitrarily close to 1.

On the other hand, Rutten et al. (2022) considers the problem of CFC with \( \alpha \)-polyhedral hitting costs (\( \alpha \)-CFC), but with the convexity assumption dropped from the hitting costs \( f_t \). They obtain a \((1 + \epsilon)\)-consistent, \( 2^{\tilde{O}\left(\frac{1}{\epsilon^\alpha}\right)} \)-robust algorithm in this setting, together with a lower bound showing that this exponential trade-off between robustness and consistency is necessary due to their non-convex setting. Their algorithm is a switching algorithm and crucially depends on the \( \alpha \)-polyhedral structure of the hitting cost functions, and hence cannot be extended to general CFC. The authors also propose an algorithm for CFC in the 1-dimensional case (where \( X = \mathbb{R} \)) that achieves \((1 + \epsilon)\)-consistency and \( O\left(\frac{1}{\epsilon^2}\right) \) robustness, and they prove a lower bound of \((1 + \epsilon)\)-consistency and \( O\left(\frac{1}{\epsilon}\right) \) robustness on any algorithm for CFC with black-box advice. They leave open the broader problem of developing robust and consistent algorithms for CFC and its many subclasses in the higher-dimensional setting.

1.3. Notation

Throughout this paper \( X \) refers to a real vector space of arbitrary dimension. When a norm \( \| \cdot \| \) is distinguished, \( B(x, r) \) is the closed \( \| \cdot \| \)-ball of radius \( r \geq 0 \) centered at \( x \), and \( \Pi_K x \) is a metric projection of the point \( x \in X \) onto a closed convex set \( K \). For \( x, y \in X \), we define \( [x, y] := \{ z \in X : z = \lambda x + (1 - \lambda)y, \lambda \in [0, 1] \} \) as the convex span of \( x \) and \( y \). The non-negative reals are denoted by \( \mathbb{R}_+ \), and for \( T \in \mathbb{N} \), we write \( [T] := \{1, \ldots, T\} \). Asymptotic notation involving the variable \( \epsilon > 0 \) reflects the asymptotic regime \( \epsilon \to 0 \).

2. Preliminaries

We consider the general problem of convex function chasing (CFC) on a real normed vector space \( X = (X, \| \cdot \|) \). In particular, we make no assumption on either the dimension of \( X \) or on the choice of norm \( \| \cdot \| \). In CFC, a decision-maker begins at some initial point \( x_0 \in X \), and at each time \( t \in \mathbb{N} \) is handed a convex function \( f_t : X \to \mathbb{R}_+ \) and must choose some \( x_t \in X \), paying both the hitting cost \( f_t(x_t) \), as well as the movement or switching cost \( \|x_t - x_{t-1}\| \) induced by the norm. Crucially, \( x_t \) is chosen prior to the revelation of any future cost functions \( f_k, k > t \), i.e., decisions are made online. The game ends at some time \( T \in \mathbb{N} \), which is unknown to the decision-maker in advance. We refer to a tuple \((x_0, f_1, \ldots, f_T)\) as an instance of the CFC problem. The total cost incurred by the decision-maker on a problem instance is \( \sum_{t=1}^T f_t(x_t) + \|x_t - x_{t-1}\| \).

Informally, an online algorithm for CFC is an algorithm that, on a given instance of CFC, produces decisions online. We denote by \( \text{ALG}_t \) the \( t \)th decision made by an online algorithm \( \text{ALG} \); by convention, \( \text{ALG}_0 := x_0 \), the starting point of the instance. Then the cost \( C_{\text{ALG}} \) incurred by \( \text{ALG} \)
on an instance is
\[ C_{ALG} = \sum_{t=1}^{T} f_t(\text{ALG}_t) + \|\text{ALG}_t - \text{ALG}_{t-1}\|. \]

We also introduce the partial cost notation \( C_{ALG}(t, t') = \sum_{i=t}^{t'} f_i(\text{ALG}_i) + \|\text{ALG}_i - \text{ALG}_{i-1}\|, \)
defined for \( 1 \leq t \leq t' \leq T \). We refer to the set of all online algorithms for CFC as \( \mathcal{A}_{CFC} \).

We typically compare online algorithms for CFC against \( \text{OPT} \), the offline optimal algorithm that chooses the hindsight optimal sequence of decisions for any problem instance. Its cost is the optimal value of the following convex program:

\[ C_{OPT} = C_{OPT}(x_0, f_1, \ldots, f_T) := \min_{x_1, \ldots, x_T \in X} \sum_{t=1}^{T} f_t(x_t) + \|x_t - x_{t-1}\| \]

and its decisions are determined by the optimal solution. To evaluate the performance of an online algorithm for CFC, we consider the competitive ratio, which measures the worst case ratio in costs between an algorithm and \( \text{OPT} \). In the following, we define both the conventional competitive ratio as well as a generalization that allows for comparing against arbitrary benchmark algorithms.

**Definition 1** Let \( \text{ALG}^{(1)} \) be an online algorithm for CFC, and let \( \text{ALG}^{(2)} \) be another (not necessarily online) algorithm for CFC. \( \text{ALG}^{(1)} \) is defined to be \( C \)-competitive with respect to \( \text{ALG}^{(2)} \) if, regardless of problem instance, \( C_{ALG}^{(1)} \leq C \cdot C_{ALG}^{(2)} \). In particular, if \( \text{ALG}^{(2)} = \text{OPT} \), we simply say that \( \text{ALG}^{(1)} \) is \( C \)-competitive, or has competitive ratio \( C \).

### 2.1. Subclasses of Convex Function Chasing

CFC is a broad set of problems and many subclasses have received attention in the literature. We consider several subclasses of the general CFC problem in this work, distinguished by different assumptions on the hitting cost functions. In this section, we briefly define the subclasses of CFC which we refer to in our later results in the main text. We give more detailed definitions of these and several other subclasses of CFC in Appendix A.1.

#### 2.1.1. Convex Body Chasing

In the problem of convex body chasing (CBC), the decision-maker must choose each decision \( x_t \) from a convex body \( K_t \subseteq X \) that is revealed online. This can be seen as a special case of CFC where \( f_t \) is 0 on \( K_t \) and \( \infty \) elsewhere; see Appendix A.1.1 for more details on this equivalence. A notable special case of CBC is the problem of nested convex body chasing (NCBC), in which subsequent bodies are nested, i.e., \( K_t \supseteq K_{t+1} \) for each \( t \). We define \( \mathcal{A}_{CBC} \) as the set of all online algorithms for CBC that are feasible, i.e., that produce decisions within the convex body \( K_t \) at each time. We define \( \mathcal{A}_{NCBC} \) similarly as the set of feasible online algorithms for NCBC.

#### 2.1.2. \( \alpha \)-Polyhedral Convex Function Chasing

Several subclasses of CFC have been studied in the literature with hitting cost functions \( f_t \) restricted so as to enable dimension-free competitive ratios. One of the most well-studied such subclasses is

---

1. Like \( \text{OPT} \), the decision of \( \text{ALG}^{(2)} \) at some time \( t \) is allowed to depend on problem instance data revealed after time \( t \).
the problem of $\alpha$-polyhedral convex function chasing ($\alpha$CFC), e.g. Chen et al. (2018); Zhang et al. (2021), in which each hitting cost function $f_t$ is restricted to be globally $\alpha$-polyhedral, meaning intuitively that it has a unique minimizer, away from which it grows with slope at least $\alpha > 0$.

**Definition 2** Let $(X, \| \cdot \|)$ be a normed vector space, and let $\alpha > 0$. A function $f : X \to \mathbb{R}_+$ is **globally $\alpha$-polyhedral** if it has unique minimizer $x^* \in X$, and in addition,

$$f(x) \geq f(x^*) + \alpha \| x - x^* \| \quad \text{for all } x \in X.$$  

2.2. Using Black-Box Advice: Robustness, Consistency, and Bicompetitive Analysis

In this work, we seek algorithms for CFC and its subclasses that can exploit the good performance of a black-box advice algorithm, such as a reinforcement learning model, while maintaining rigorous worst-case performance guarantees. More specifically, we strive for algorithms that can obtain cost not much worse than optimal when the black-box advice is perfect, yet which have uniformly bounded competitive ratio when the advice is arbitrarily bad or even adversarial. This dual objective is naturally formulated in terms of robustness and consistency, which were introduced by Lykouris and Vassilvtiskii (2018) and are defined as follows.

**Definition 3** Let $\text{ALG}$ be an online algorithm for CFC, and let $\text{ADV}$ be a black-box advice algorithm. $\text{ALG}$ is said to be $c$-**consistent** if it is $c$-competitive with respect to $\text{ADV}$. On the other hand, $\text{ALG}$ is defined to be $r$-**robust** if it is $r$-competitive, independent of the performance of $\text{ADV}$.

Our precise goal is to design algorithms achieving $(1 + \epsilon)$-consistency and $R(\epsilon)$-robustness for CFC and its subclasses, where $\epsilon > 0$ is a hyperparameter chosen by the decision-maker that encodes confidence in the advice. The dependence of the robustness $R(\epsilon)$ on $\epsilon$ anticipates a trade-off between exploiting advice and worst-case robustness. We ideally seek algorithms with robustness $R(\epsilon)$ as small as possible, so that the trade-off between consistency and robustness is tight.

Our methodology for designing robust and consistent algorithms is very general, in the sense that we do not restrict to any special cases of CFC and do not consider in our analysis the explicit behavior of the advice or of any specific algorithm for CFC. This is in contrast to the work of Rutten et al. (2022), whose main robustness and consistency guarantees depend crucially upon the $\alpha$-polyhedral setting. Rather, we approach the task of designing robust and consistent algorithms via a more general problem of designing bicompetitive meta-algorithms for CFC, which, informally, are “recipes” for combining two CFC algorithms to produce a single algorithm with competitive guarantees with respect to both input algorithms. More formally, we give the following definitions.

**Definition 4** An online algorithm $\text{ALG}$ for CFC is $(c, r)$-**bicompetitive** with respect to a pair of algorithms $(\text{ALG}^{(1)}, \text{ALG}^{(2)})$ if $\text{ALG}$ is simultaneously $c$-competitive with respect to $\text{ALG}^{(1)}$ and $r$-competitive with respect to $\text{ALG}^{(2)}$. Equivalently, the cost of $\text{ALG}$ can be bounded as

$$C_{\text{ALG}} \leq \min \{ c \cdot C_{\text{ALG}^{(1)}}, r \cdot C_{\text{ALG}^{(2)}} \}.$$  

**Definition 5** A meta-algorithm $\text{META}$ for CFC is a mapping $\text{META} : \mathcal{A}_{\text{CFC}} \times \mathcal{A}_{\text{CFC}} \to \mathcal{A}_{\text{CFC}}$. That is, $\text{META}$ takes as input two online algorithms for CFC and returns a single online algorithm for the problem. $\text{META}$ is said to be $(c, r)$-**bicompetitive** if its output is always $(c, r)$-bicompetitive with respect to its inputs.
It follows immediately from the previous two definitions that if \( \text{META} \) is \((c, r)\)-bicompetitive, \( \text{ADV} \) is the advice, and \( \text{ROB} \) is a \( b \)-competitive algorithm for (a subclass of) \( \text{CFC} \), then \( \text{META}(\text{ADV}, \text{ROB}) \) is \( c \)-consistent and \( rb \)-robust. We discuss this observation in more detail in Appendix A.2. Thus bicompetitive meta-algorithms give a general approach for designing robust and consistent algorithms for \( \text{CFC} \) and its subclasses.

The idea of approaching robust and consistent algorithm design via the design of bicompetitive meta-algorithms has been considered to some extent in the literature on other online problems, e.g., in the work of Antoniadis et al. (2020) on combining algorithms for MTS. To our knowledge, however, our specific terminology has not seen wide use in the literature.

3. Warmup: Switching Algorithms and Their Fundamental Limits

A natural first approach for designing bicompetitive meta-algorithms for \( \text{CFC} \) is to consider the class of switching algorithms, whose decisions switch between two other algorithms:

**Definition 6** A meta-algorithm \( \text{META} \) is a **switching meta-algorithm** if, at each time \( t \), the decision \( \text{META}_t(\text{ALG}^{(1)}, \text{ALG}^{(2)}) \) made by \( \text{META} \) resides in the set \( \{\text{ALG}^{(1)}_t, \text{ALG}^{(2)}_t\} \).

Switching algorithms have garnered significant attention in the literature on robustness and consistency in recent years, e.g., Antoniadis et al. (2020); Lee et al. (2021); Angelopoulos (2021); Rutten et al. (2022). In particular, the only robust and consistent algorithms for \( \text{CFC} \) or subclasses thereof in general dimension are the switching algorithms of Antoniadis et al. (2020) for MTS and Rutten et al. (2022) for \( \alpha \text{CFC} \). In the following proposition, we refine these prior results, showing the existence of a switching meta-algorithm for general \( \text{CFC} \) with tunable bicompetitive bound.

**Proposition 7** Suppose \( \text{ADV}, \text{ROB} \) are algorithms for \( \text{CFC} \) and \( C_{\text{ROB}} \geq 1 \). There is a switching meta-algorithm \( \text{SWITCH} \) (Appendix B, Algorithm 4) that is \((3 + \mathcal{O}(\epsilon), 5 + \mathcal{O}(\frac{1}{\epsilon^2}))\)-bicompetitive with respect to the inputs \( (\text{ADV}, \text{ROB}) \), where \( \epsilon > 0 \) is an algorithm hyperparameter.

Our proof of Proposition 7 follows closely that of (Antoniadis et al., 2020, Theorem 1), extending it via the recent result of (Angelopoulos, 2021, Theorem 5) on linear search with a “hint”; we present a proof in Appendix B.2.

If \( \text{ADV} \) is an advice algorithm and \( \text{ROB} \) is a \( C \)-competitive algorithm for (a subclass of) \( \text{CFC} \), then \( \text{SWITCH} \) yields \((3 + \mathcal{O}(\epsilon))\)-consistency and \((5 + \mathcal{O}(\frac{1}{\epsilon^2}))C\)-robustness. Notably, this does not appear to allow for arbitrary consistency: specifically, \( \text{SWITCH} \) cannot attain consistency less than 3 while maintaining finite robustness. This limitation is unsurprising, since an identical lower bound holds on the algorithm for linear search on which \( \text{SWITCH} \) is based (Angelopoulos, 2021, Theorem 7), which can be extended to a lower bound on the bicompetitiveness of switching meta-algorithms. It is natural, then, to ask whether this lower bound also applies to the robustness and consistency of \( \text{CFC} \) algorithms. That is, can we devise a switching algorithm that, so long as it is provided with some non-adversarial, competitive algorithm \( \text{ROB} \), beats 3-consistency while staying robust?

In the following theorem, which we prove in Appendix B.3, we show that robustness and consistency also face this fundamental limit: any algorithm that switches between black-box advice and an advice-agnostic competitive algorithm cannot beat 3-consistency while preserving robustness. We prove the theorem in the \( l^2 \) setting, though the result extends to other norms such as the \( l^\infty \) norm.
Algorithm 1: \textsc{NestedSwitch}(\textsf{ADV}, \textsf{ROB}; \epsilon, r)

\textbf{Input:} Algorithms \textsf{ADV}, \textsf{ROB} \in \mathcal{A}_{\text{NCBC}}; hyperparameters \( \epsilon, r > 0 \)

\textbf{Output:} Decisions \( x_1 \in K_1, \ldots, x_T \in K_T \) chosen online

\begin{algorithmic}[1]
\FOR \text{for} \( t = 1, 2, \ldots, T \) \DO
\STATE Observe \( K_t, \bar{x}_t \coloneqq \textsf{ADV}_t \), and \( s_t \coloneqq \textsf{ROB}_t \)
\IF \( \epsilon \cdot C_{\textsf{ADV}}(1, t) \geq r(d + 2) \)
\STATE \( x_t \leftarrow s_t \)
\ELSE
\STATE \( x_t \leftarrow \bar{x}_t \)
\ENDIF
\ENDFOR
\end{algorithmic}

Theorem 8 \textit{Consider the} \( \ell^2 \) \textit{norm setting. Let} \textsf{ADV} \textit{be an advice algorithm, and let} \textsf{ROB} \textit{be any (deterministic) competitive algorithm for CBC that is advice-agnostic. Let} \textsf{ALG} \textit{be an online algorithm that switches between} \textsf{ADV} \textit{and} \textsf{ROB}. \textit{If} \textsf{ALG} \textit{is} \( c \)-consistent with \( c < 3 \), \textit{then} \textsf{ALG} \textit{cannot have finite robustness.}

This lower bound implies that to obtain finite robustness alongside consistency \( c < 3 \) for general CFC, one must venture beyond the realm of switching algorithms. This is exactly the focus of Section 4, where we approach this task by exploiting the convexity of CFC. First, though, we ask: are there any special cases of CFC in which switching algorithms \textit{can} obtain \((1 + \epsilon)\)-consistency and finite robustness for any \( \epsilon > 0 \)? The answer is affirmative for \( \alpha \)CFC (Rutten et al. (2022)), and as we show in the next proposition, such an algorithm also exists for NCBC. Specifically, we propose an algorithm, \textsc{NestedSwitch} (Algorithm 1), which can achieve a \((1 + \epsilon)\)-consistent, \( O(d) \)-robust trade-off for NCBC by using a simple threshold-based rule for switching between the advice and the Steiner point algorithm of Bubeck et al. (2019). We prove Proposition 9 in Appendix B.4.

Proposition 9 \textit{Consider the problem of NCBC on} \((\mathbb{R}^d, \| \cdot \|_{\ell^2})\), \textit{where the initial body} \( K_1 \textit{resides in some ball} B(y, r) \textit{of radius} r \textit{containing} x_0 \textit{, and} C_{\text{OPT}} \geq 1 \). \textit{If} \textsf{ROB} \textit{is the Steiner point algorithm (Bubeck et al. (2019)) that chooses the Steiner point of} \( K_t \textit{at each time} t \), \textit{then} \textsc{NestedSwitch} \textit{(Algorithm 1)} \textit{is} \((1 + \epsilon)\)-consistent and \( (1 + \frac{1}{\epsilon}) r(d + 2)\)-robust, \textit{where} \( \epsilon > 0 \textit{is a hyperparameter.}

4. Beyond Switching Algorithms: Exploiting Convexity to Break 3-Consistency

In this section, we present our main results: two novel meta-algorithms that transcend the limitations of switching algorithms by exploiting the convexity of CFC. The key insight that enables this improved performance is that \textit{hedging} between \textsf{ADV} and \textsf{ROB}, i.e., choosing a decision that is a convex combination of the two, allows for more nuanced algorithm behavior than switching permits.

4.1. \textsc{Interp}: a \((\sqrt{2} + \epsilon, O(\epsilon^{-2}))\)-Bicompetitive Meta-Algorithm

We preface our first algorithm with some definitions from the geometry of real normed vector spaces \( X = (X, \| \cdot \|) \) which we employ in the algorithm’s statement and performance bound. We present abridged introductions of these notions here, giving more detail in Appendix C.
We begin by introducing the \textit{rectangular constant} \( \mu(\mathcal{X}) \) of a normed vector space \( \mathcal{X} \), which is bounded between \( \sqrt{2} \) and \( 3 \), with \( \mu(\mathcal{X}) = \sqrt{2} \) when \( \mathcal{X} \) is Hilbert and \( \mu(p) < 3 \) for any \( p \in (1,\infty) \) (Joly (1969); Baronti et al. (2021)). Next, we define the \textit{radial retraction}.

**Definition 10 (Rieffel (2006))** \( \) On a normed vector space \( \mathcal{X} = (X, \| \cdot \|) \), the radial retraction \( \rho(\cdot; r) : X \to B(0, r) \) is the metric projection onto the closed ball of radius \( r \geq 0 \):

\[
\rho(x; r) = \begin{cases} x & \text{if} \|x\| \leq r \\ r \frac{x}{\|x\|} & \text{if} \|x\| > r. \end{cases}
\]

On a fixed normed space \( \mathcal{X} \), the collection of radial retractions \( \rho(\cdot; r) \) with \( r > 0 \) share a Lipschitz constant, which we call \( k(\mathcal{X}) \). It is known that \( 1 \leq k(\mathcal{X}) \leq 2 \) (Thele (1974)), and moreover \( k(\mathcal{X}) \leq \mu(\mathcal{X}) \) (Appendix C, Proposition 22).

With these definitions at our disposal, we now proceed to the main result of this section. We propose Algorithm 2, a meta-algorithm INTERP that takes as input two algorithms ADV, ROB for (a subclass of) CFC, and hyperparameters \( \epsilon, \gamma, \delta > 0 \) satisfying \( 2\gamma + 2\delta = \epsilon \). INTERP works as follows: at each time \( t \), if the cost of ROB so far is a substantial fraction of the cost of ADV, then INTERP can move to ADV, while staying competitive with respect to ROB, and it does so (line 4). Otherwise, INTERP moves to a point \( x_t \) determined by the series of radial projections (lines 6, 7, and 8), which intuitively guide INTERP to take a “greedy step” toward the decision made by ROB while still remaining close enough to ADV so as to maintain a consistency guarantee.

**Algorithm 2:** INTERP(ADV, ROB; \( \epsilon, \gamma, \delta \))

\[
\text{Input:} \text{ Algorithms ADV, ROB; hyperparameters } \epsilon > 0 \text{ and } \gamma > 0, \delta > 0 \text{ satisfying } 2\gamma + 2\delta = \epsilon \\
\text{Output:} \text{ Decisions } x_1, \ldots, x_T \text{ chosen online} \\
1 \text{ for } t = 1, 2, \ldots, T \text{ do} \\
2 \quad \text{Observe } f_t, \hat{x}_t := \text{ADV}_t, \text{ and } s_t := \text{ROB}_t \\
3 \quad \text{if } C_{\text{ROB}}(1, t) \geq \delta \cdot C_{\text{ADV}}(1, t) \text{ then} \\
4 \quad \quad x_t := \hat{x}_t \\
5 \quad \text{else} \\
6 \quad \quad y_t := s_{t-1} + \rho \left( \hat{x}_{t-1} - s_{t-1}; \|x_{t-1} - s_{t-1}\| \right) \\
7 \quad \quad z_t := s_{t-1} + \rho \left( y_t - s_{t-1}; \max\{\|y_t - s_{t-1}\| - \gamma \cdot C_{\text{ADV}}(t, t), 0\} \right) \\
8 \quad \quad x_t := s_t + \rho \left( \hat{x}_t - s_t; \|z_t - s_{t-1}\| \right) \\
9 \text{ end}
\]

We characterize the bicompetitive performance of INTERP in the following theorem, which holds in any normed vector space \( \mathcal{X} \) of arbitrary dimension.

**Theorem 11** INTERP (Algorithm 2) is

\[
\left( \mu(\mathcal{X}) + 1 + \frac{k(\mathcal{X})}{\gamma} + \frac{\mu(\mathcal{X}) + \epsilon}{\delta} \right) -\text{bicompetitive}
\]

with respect to (ADV, ROB). With \( \gamma, \delta \) chosen optimally, the bound is \( \mu(\mathcal{X}) + \epsilon, \mathcal{O}(\epsilon^{-2}) \).

In particular, if ADV is advice and ROB is \( C \)-competitive for (a subclass of) CFC, then INTERP is \( \mu(\mathcal{X}) + \epsilon \)-consistent and \( \mathcal{O}(C\epsilon^{-2}) \)-robust.
Notably, \textsc{interp} (Algorithm 2) strictly improves on the 3-consistent lower bound for switching meta-algorithms in any $l^p$ space with $1 < p < \infty$, in which it holds that $\mu(l^p) < 3$. Moreover, it obtains consistency $(\sqrt{2} + \epsilon)$ in any Hilbert space. We prove Theorem 11 and give details regarding optimal selection of the parameters $\gamma, \delta$ in Appendix D. The proof employs two potential function arguments with different potential functions for the bounds with respect to $\text{ADV}$ and $\text{ROB}$. Moreover, the generality of the theorem’s setting requires the development of several geometric results characterizing the radial projection and its relation to the rectangular constant in arbitrary-dimensional normed vector spaces, which we present in Appendix D.1 prior to the main proof. These results are crucial for enabling \textsc{interp}’s robustness and consistency in the general setting and elucidate the presence of the constants $\mu(\mathcal{X})$ and $k(\mathcal{X})$ in its bicompetitive bound.

We also detail robustness and consistency corollaries of Theorem 11 for multiple subclasses of CFC in Appendix F. In particular, Theorem 11 and Table 1 imply an algorithm for CFC and CBC on $\mathbb{R}^d$ with any norm that is $(\mu(\mathbb{R}^d, \| \cdot \|) + \epsilon)$-consistent and $O(\frac{\epsilon}{d^2})$-robust; we also obtain an algorithm for $\alpha$CFC that is $(\mu(\mathcal{X}) + \epsilon)$-consistent and $O(\frac{1}{\alpha \epsilon^2})$-robust for $\alpha$CFC on any normed vector space $\mathcal{X}$.

4.2. Attaining $(1 + \epsilon)$-Consistency in Bounded Instances with \textsc{bdinterp}

In the preceding section, we proved that in the Hilbert space setting, \textsc{interp} (Algorithm 2) obtains consistency $(\sqrt{2} + \epsilon)$ while remaining competitive with respect to $\text{ROB}$. While this is a significant improvement on the limit of 3-consistency faced by switching algorithms, the question remains: can we devise an algorithm that achieves $(1 + \epsilon)$-consistency and $R(\epsilon) < \infty$ competitiveness with respect to $\text{ROB}$ for any $\epsilon > 0$, in any normed vector space? In this section, we provide a simple sufficient condition under which this is possible: if there exists some constant $D \in \mathbb{R}_+$ for which $\| \text{ADV}_t - \text{ROB}_t \| \leq D$ for all $t$, then there is a meta-algorithm that is $(1 + \epsilon, O(D))$-bicompetitive with respect to $(\text{ADV}, \text{ROB})$. We call this condition $D$-boundedness of $\text{ADV}$ and $\text{ROB}$; it arises naturally in a number of settings, for example in any CBC instance in which the diameter of each body $K_t$ is bounded by $D$.

We present the algorithm achieving this bicompetitive bound, \textsc{bdinterp}, in Algorithm 3. Just like \textsc{interp}, \textsc{bdinterp} takes as input two algorithms $\text{ADV}, \text{ROB}$ for (a subclass of) CFC, and hyperparameters $\epsilon, \gamma, \delta > 0$ satisfying $2\gamma + 2\delta = \epsilon$. At a high level, \textsc{bdinterp} operates similarly to \textsc{interp}, though it takes smaller greedy steps toward $\text{ROB}$, enabling it to maintain $(1 + \epsilon)$-consistency. Specifically, \textsc{bdinterp} works as follows: if the cost of $\text{ROB}$ is a sufficient fraction of the cost of $\text{ADV}$, then $\text{bdinterp}$ moves to $\text{ADV}_t$ (line 4). Otherwise, it selects an auxiliary point $y_t$ as the point along the segment $[s_t, x_t]$ with the same relative position as $x_{t-1}$ on the segment $[s_{t-1}, \bar{x}_{t-1}]$ (line 7), and then chooses $x_t$ by taking a greedy step toward $s_t$ from $y_t$ (line 8).

We present the performance result for $\text{bdinterp}$ in Theorem 12; like Theorem 11, the result holds in any normed vector space $\mathcal{X}$ of arbitrary dimension.

**Theorem 12** Suppose that $\text{ADV}$ and $\text{ROB}$ are $D$-bounded, i.e., $\| \text{ADV}_t - \text{ROB}_t \| \leq D$ for all $t \in [T]$; and assume that $C_{ROB} \geq 1$. Then $\text{bdinterp}$ (Algorithm 3) is

$$\left(1 + \epsilon, D + \frac{D}{\gamma} + \frac{1 + \epsilon}{\delta}\right)$$ bicompetitive

with respect to $(\text{ADV}, \text{ROB})$. With $\gamma, \delta$ chosen optimally, the bound is $(1 + \epsilon, O(D))$. 

11
Algorithm 3: BDINTERP(ADV, ROB; $\epsilon, \gamma, \delta$)

**Input:** Algorithms ADV, ROB; hyperparameters $\epsilon > 0$ and $\gamma > 0$, $\delta > 0$ satisfying $2\gamma + 2\delta = \epsilon$

**Output:** Decisions $x_1, \ldots, x_T$ chosen online

1. for $t = 1, 2, \ldots, T$ do
2.   Observe $f_t, \tilde{x}_t := \text{ADV}_t$, and $s_t := \text{ROB}_t$
3.   if $C_{\text{ROB}}(1, t) \geq \delta \cdot C_{\text{ADV}}(1, t)$ then
4.     $x_t \leftarrow \tilde{x}_t$
5.   else
6.     $\nu \leftarrow \frac{\|x_{t-1} - s_{t-1}\|}{\|x_{t-1} - s_{t-1}\|}$ if $\tilde{x}_{t-1} \neq s_{t-1}$, otherwise $\nu \leftarrow 0$
7.     $y_t \leftarrow \nu \tilde{x}_t + (1 - \nu) s_t$
8.     $x_t \leftarrow s_t + \rho (y_t - s_t; \max\{\|y_t - s_t\| - \gamma \cdot C_{\text{ADV}}(t, t), 0\})$
9. end

In particular, if ADV is advice and ROB is $C$-competitive for (a subclass of) CFC, then BDINTERP is $(1 + \epsilon)$-consistent and $O(\frac{CD}{\epsilon})$-robust.

Remarkably, Theorem 12 states that BDINTERP not only improves on the consistency of INTERP, but it also strictly improves upon INTERP’s $O(\epsilon^{-2})$ competitiveness with respect to ROB when $D = o(\epsilon^{-1})$. Moreover, BDINTERP substantially improves on the randomized switching algorithm of Antoniadis et al. (2020) in the $D$-bounded setting, providing deterministic and tunable robustness and consistency guarantees with no additive factor in the consistency term. We give a proof of Theorem 12, as well as details on optimal parameter selection, in Appendix E. The argument follows a similar line of reasoning as that of our proof of Theorem 11, though in the proof of competitiveness with respect to ROB (i.e., robustness), we employ a novel potential function constructed via the ratio between the respective distances of $x_t$ and $\tilde{x}_t$ to $s_t$.

We detail robustness and consistency corollaries of Theorem 12 for multiple subclasses of CFC in Appendix F. In particular, Theorem 12 and Table 1 imply an algorithm for CFC and CBC with any norm that is $(1 + \epsilon)$-consistent and $O(\frac{D}{\epsilon})$-robust on $D$-bounded instances. We also obtain an algorithm for $\alpha$CFC in the $D$-bounded finite-dimensional Euclidean setting that achieves $(1 + \epsilon)$-consistency and $O(\frac{D}{\alpha + 2\epsilon})$-robustness. This latter bound is nearly tight for $\alpha$CFC: Rutten et al. (2022, Theorem 3.6) prove a lower bound of $O(\frac{1}{\alpha})$ robustness for any $(1 + \epsilon)$-consistent $\alpha$CFC algorithm. Choosing $\epsilon = \alpha$, Theorem 12 gives us $(1 + \alpha)$-consistency and $O(\frac{1}{\alpha + 2})$-robustness when $D = O(1)$ in $\alpha$, leaving a gap of just $O(\alpha^{-1/2})$ between the upper and lower bounds. We leave to future work the question of whether the upper and lower bounds can be made tight and whether the factor of $D$ (and more generally the $D$-boundedness assumption) can be dropped.

5. Conclusion

In this work, we examine the question of integrating black-box advice into algorithms for convex function chasing using the notions of robustness and consistency from the literature on online algorithms with machine-learned advice. We first propose an algorithm that switches between the decisions of an arbitrary $C$-competitive algorithm ROB and the advice, showing that it obtains $(3 + O(\epsilon))$-consistency and finite robustness for any $\epsilon > 0$. We moreover show that this is optimal, in the sense that no switching algorithm can improve upon 3-consistency while maintaining
finite robustness. We then move beyond switching algorithms, and propose two algorithms, INTERP and BdINTERP, which obtain improved robustness and consistency guarantees by exploiting the convexity inherent in the CFC problem. In particular, INTERP obtains $O(\sqrt{2} + \epsilon)$-consistency and $O(E^2)$-robustness, and under the additional assumption of $D$-boundedness, BdINTERP can obtain $(1 + \epsilon)$-consistency and $O(CD)$-robustness. We show that BdINTERP is nearly optimal for the problem of CFC with $\alpha$-polyhedral hitting cost functions $f_t$, so long as $D = O(1)$ in $\alpha$.

Several interesting questions remain open for future work: in particular, (a) the question of whether $(1 + \epsilon)$-consistency and finite robustness can be obtained for general CFC without the $D$-boundedness assumption, and (b) the question of tight lower bounds on robustness and consistency for CFC and its many subclasses. Specifically, for the case of CFC in general, we pose the question of whether $(1 + \epsilon)$-consistency is possible together with $O(d)$-robustness, or even whether the dependence on $\epsilon$ and $d$ can be further improved in the robustness bound.

### Appendix A. Preliminaries

In part A.1 of this appendix, we provide more detailed definitions of the subclasses of convex function chasing considered in this work, including both those introduced in Section 2.1 as well as several additional special cases which we refer to in the robustness and consistency results given in Appendix F. We also review state-of-the-art competitive algorithms for each subclass, which we summarize in Table 2, which is an extended version of Table 1 in the main text. Then, in part A.2, we elaborate on the claim made in Section 2.2 that a \((c, r)\)-bicompetitive meta-algorithm for CFC, along with a \(b\)-competitive algorithm for a subclass of CFC, together yield a \(c\)-consistent and \(rb\)-robust algorithm for that subclass.

Table 2: Competitive ratios for state-of-the-art algorithms on various subclasses of CFC.
A.1. Subclasses of CFC

A.1.1. Convex Body Chasing

In the problem of convex body chasing (CBC) on a normed vector space \((X, \| \cdot \|)\), at each time \(t\) a decision-maker is given a convex body \(K_t \subseteq X\) and faces the requirement that their decision \(x_t\) must reside within \(K_t\). A further special case of CBC is the problem of nested convex body chasing (NCBC), in which subsequent bodies are nested, i.e. \(K_t \supseteq K_{t+1}\) for each \(t\). We define the set of all online algorithms which are feasible for CBC, i.e. which produce decisions residing within the convex body \(K_t\) at each time, as \(A_{\text{CBC}}\). We define \(A_{\text{NCBC}}\) similarly as the set of all online algorithms which are feasible for NCBC. Sellke (2020) proved that an algorithm based on a functional generalization of the Steiner point of a convex body achieves competitive ratio \(d\) for CBC and \(d + 1\) for general CFC in \(\mathbb{R}^d\) equipped with any norm.

The problem of convex body chasing can easily be seen as a special case of CFC in which each hitting cost \(f_t\) is the \(\{0, \infty\}\) indicator of the convex set \(K_t\). That is,

\[
f_t(x) = \begin{cases} 
0 & \text{if } x \in K_t \\
\infty & \text{otherwise.}
\end{cases}
\]

As noted in Sellke (2020), we need not even require hitting costs to take infinite values to recover convex body chasing from function chasing. Indeed, restricting to the finite-dimensional setting, consider \(f_t\) defined as

\[
f_t(x) = 3 \cdot d(x, K_t) = 3 \min_{y \in K_t} \| x - y \|.
\]

Then any algorithm \(\text{ALG} \in A_{\text{CFC}}\) yields a set of decisions \(\text{ALG}_1, \ldots, \text{ALG}_T\) on the instance \((x_0, f_1, \ldots, f_T)\); and moreover, \(\text{ALG}\) can be transformed into an algorithm \(\text{ALG}' \in A_{\text{CFC}}\) with strictly improved cost, and which in particular incurs no hitting cost, by setting

\[
\text{ALG}'_t = \begin{cases} 
\text{ALG}_t & \text{if } \text{ALG}_t \in K_t \\
\Pi_{K_t} \text{ALG}_t & \text{otherwise.}
\end{cases}
\]

Clearly each decision \(\text{ALG}'_t\) resides in the convex body \(K_t\); thus \(\text{ALG}'\) is a feasible online algorithm for CBC, i.e., \(\text{ALG}' \in A_{\text{CBC}}\). Moreover, the cost of \(\text{ALG}'\) on the CBC instance is identical to its cost for the corresponding CFC instance, since it incurs no hitting cost. It follows that the competitive ratio of \(\text{ALG}'\) for the CBC problem is at most the competitive ratio of \(\text{ALG}\) as a CFC algorithm, since \(\text{OPT}\) for a CBC instance and its corresponding CFC instance always coincide. In short, a \(C\)-competitive algorithm for CFC is also \(C\)-competitive for CBC.

Remark 13 The preceding line of reasoning can be extended to show that a \(C\)-competitive algorithm for CFC gives a \(C\)-competitive algorithm for CBC with strict decision constraints, i.e., where at time \(t\), the decision \(x_t\) must both reside in some convex body \(K_t\) and also incurs a convex hitting cost \(f_t(x_t)\).

\[\footnote{This restriction is natural because no algorithm can be competitive for CBC in the infinite-dimensional setting. We impose the restriction in order to ensure existence of a metric projection onto \(K_t\).} \]
A.1.2. Chasing Low-dimensional Convex Bodies

A special case of convex body chasing that has received significant attention is the problem of chasing low-dimensional bodies in higher-dimensional space: indeed, the seminal work of Friedman and Linial (1993) began by addressing the problem of chasing lines in the Euclidean plane. Bienkowski et al. (2019) later presented a 3-competitive algorithm for chasing lines in \((\mathbb{R}^d, \| \cdot \|_{\ell^2})\), and most recently Argue et al. (2020) gave an algorithm that is \((2k + 1)\)-competitive for chasing convex bodies lying in \(k\)-dimensional affine subspaces, regardless of the dimension \(d\) of the underlying Euclidean space. Motivated by this last result, we define the problem of \(k\)-dimensional convex body chasing \((k\text{-CBC})\), comprised of all instances of CBC in which each body \(K_t\) lies within an affine subspace of dimension at most \(k\) – i.e., \(\dim \text{aff } K_t \leq k\) for all \(t\).

A.1.3. \(\alpha\)-Polyhedral Convex Function Chasing

A class of functions that has been studied extensively in the literature on online optimization with switching costs (SOCO) is the class of globally \(\alpha\)-polyhedral functions, e.g., Chen et al. (2018); Zhang et al. (2021), which are defined as follows.

Definition 14 Let \((X, \| \cdot \|)\) be a normed vector space, and let \(\alpha > 0\). A function \(f : X \rightarrow \mathbb{R}_+\) is globally \(\alpha\)-polyhedral if it has unique minimizer \(x^* \in X\), and in addition,

\[
f(x) \geq f(x^*) + \alpha \|x - x^*\| \quad \text{for all } x \in X.
\]

Roughly speaking, a globally \(\alpha\)-polyhedral function has a unique minimizer, away from which it grows with slope at least \(\alpha\). For a fixed \(\alpha > 0\), we define the problem of \(\alpha\)-polyhedral convex function chasing \((\alpha\text{-CFC})\) comprised of all those problem instances of CFC in which, in addition to being convex, each function \(f_t\) is also globally \(\alpha\)-polyhedral. \(\alpha\text{-CFC}\) has been widely studied due to its admitting algorithms with “dimension-free” competitive ratios: Zhang et al. (2021) showed that a greedy algorithm that simply moves to the minimizer \(x_t^*\) of each function \(f_t\) is \(\max\{1, \frac{2}{\alpha}\}\)-competitive for \(\alpha\text{-CFC}\) in any normed vector space. In the setting of \(\mathbb{R}^d\) with the \(\ell^2\) norm, Lin (2022) gave an algorithm augmenting the Online Balanced Descent algorithm of Chen et al. (2018) to achieve a competitive ratio of \(O\left(\frac{1}{\alpha^{1/2}}\right)\).

A.1.4. \((\kappa, \gamma)\)-Well-Centered Convex Function Chasing

Another class of functions that has received attention in the design of algorithms for subclasses of CFC with dimension-free competitive ratios is the set of \((\kappa, \gamma)\)-well-centered functions, introduced by Argue et al. (2020):

Definition 15 Let \((X, \| \cdot \|)\) be a normed vector space, and let \(\kappa, \gamma \geq 1\). A function \(f : \mathbb{R}^d \rightarrow \mathbb{R}_+\) with minimizer \(x^*\) is \((\kappa, \gamma)\)-well-centered if there exists some \(a > 0\) such that

\[
a \frac{\|x - x^*\|^\gamma}{2} \leq f(x) \leq \frac{\alpha \kappa}{2} \|x - x^*\|^\gamma \quad \text{for all } x \in X.
\]

Intuitively, the growth rate of a \((\kappa, \gamma)\)-well-centered function away from its minimizer (as measured with the “distance” \(\| \cdot \|^\gamma\)) is bounded above and below, and the ratio of these bounds is at most \(\kappa\). For fixed \(\kappa, \gamma \geq 1\), we define the problem of \((\kappa, \gamma)\)-well-centered convex function chasing \((\kappa, \gamma)\text{-CFC})\) comprised of all those problem instances of CFC in which each \(f_t\) is \((\kappa, \gamma)\)-well-centered. Argue et al. (2020) showed that the “Move towards Minimizer” algorithm is \((2 + 2\sqrt{2})^{\gamma/2} \kappa\)-competitive for \((\kappa, \gamma)\text{-CFC}) on \(\mathbb{R}^d\) equipped with the \(\ell^2\) norm.
A.2. Bicompetitive meta-algorithms give robust and consistent algorithms

In this section, we briefly justify the claim that if META is a \((c, r)\)-bicompetitive meta-algorithm for CFC, ADV is an advice algorithm, and ROB is a \(b\)-competitive online algorithm for a subclass of CFC, then META(ADV, ROB) is \(c\)-consistent and \(rb\)-robust for that subclass. This is straightforward to see for non-CBC subclasses, or more generally, for any subclass of CFC which does not involve hard constraints on the decisions \(x_t\). In particular, ROB being \(b\)-competitive means that \(C_{ROB} \leq b \cdot C_{OPT}\), and so \((c, r)\)-bicompetitiveness of META implies that both \(C_{META(ADV,ROB)} \leq c \cdot C_{ADV}\) and \(C_{META(ADV,ROB)} \leq r \cdot C_{ROB} \leq rb \cdot C_{OPT}\), as desired.

The only subclasses that require more careful justification are those, such as CBC, with hard constraints on the decisions. However, so long as the advice always gives feasible decisions – e.g., in the CBC case, \(ADV \in A_{CBC}\), so \(ADV_t \in K_t\) for each \(t\) – then we can obtain the same result by applying the reasoning from Appendix A.1.1 on equivalent CFC reformulations of instances with hard constraints. That is, on any instance of the subclass, we must simply run META(ADV, ROB) on its equivalent reformulation as a CFC instance, and we thereby obtain the same guarantees of \(c\)-consistency and \(rb\)-robustness for the subclass.

Appendix B. Switching algorithms

B.1. The meta-algorithm SWITCH

We give the meta-algorithm SWITCH, which takes as hyperparameters \(b > 1\) and \(\delta \in (0, 1]\), in Algorithm 4. In order to reduce the two hyperparameters \(b, \delta\) to a single hyperparameter \(\epsilon\) as in the statement of Proposition 7, we simply introduce an auxiliary variable \(\gamma\) and make the substitutions \(\delta \leftarrow b \gamma^2 - b^{-1}, b \leftarrow \sqrt{\gamma^{-2} + 1}, \) and \(\gamma \leftarrow \sqrt{\frac{T}{4}}\).

Algorithm 4: SWITCH(ADV, ROB; b, \(\delta\))

Input: Algorithms ADV, ROB \(\in A_{CFC}\); hyperparameters \(b > 1, \delta \in (0, 1]\)
Output: Decisions \(x_1, \ldots, x_T\) chosen online

\[
\begin{align*}
1 & \quad i \leftarrow 0 \\
2 & \quad \textbf{while problem instance has not ended do} \\
3 & \quad \quad \textbf{if } i \equiv 0 \ \mod 2 \textbf{ then} \\
4 & \quad \quad \quad x_t \leftarrow \text{ADV}_t \text{ until the last time } t \text{ that } C_{ADV}(1, t) \leq b^i \\
5 & \quad \quad \quad i \leftarrow i + 1 \\
6 & \quad \quad \textbf{else} \\
7 & \quad \quad \quad x_t \leftarrow \text{ROB}_t \text{ until the last time } t \text{ that } C_{ROB}(1, t) \leq \delta b^i \\
8 & \quad \quad \quad i \leftarrow i + 1 \\
9 & \quad \end{align*}
\]

B.2. Proof of Proposition 7

The proof follows the argument of (Angelopoulos, 2021, Theorem 5) and uses a similar line of reasoning as (Antoniadis et al., 2020, Theorems 1, 18) in applying an algorithm for linear search to CFC.
Each value of \( i \) encountered in the execution of Algorithm 4 is taken to refer to a phase of the algorithm; every decision \( x_t \) made during a particular value of \( i \) is said to take place during the \( i \)th phase. Our strategy will be to bound the cost that the algorithm incurs in each phase \( i \), including the cost it takes to switch from the last decision of the previous phase \( i - 1 \).

As a base case, consider \( i = 0 \). The total cost incurred by the algorithm during this phase is bounded by \( b^i = b^0 = 1 \), by line 4 of the algorithm.

Now consider phase \( i > 0 \), and assume that \( i \) is odd; after proving the cost bound for phase \( i \) in the odd case, we will state the corresponding bound for the even case, which follows a nearly identical argument. Let \( \ell \) be the last timestep in the \((i - 1)\)th phase – that is, \( \ell \) is defined such that \( C_{\text{ADV}}(1, \ell + 1) > b^{i-1} \). We will assume that \( C_{\text{ADV}}(1, \ell) \leq b^{i-1} \), i.e., the algorithm makes at least one decision during phase \((i - 1)\), selecting \( x_\ell = \text{ADV}_\ell \); but the upper bound we obtain will also apply to the case where the \((i - 1)\)th phase is vacuous. Let \( \bar{\ell} \) be the last timestep corresponding to phase \( i \), i.e., \( \bar{\ell} \geq \ell \) is defined such that \( C_{\text{ROB}}(1, \bar{\ell} + 1) > \delta b^i \). If \( \bar{\ell} = \ell \), then clearly no decisions are made during phase \( i \), so no cost is incurred during this phase. On the other hand, if \( \bar{\ell} > \ell \), then certainly \( C_{\text{ROB}}(1, \bar{\ell}) \leq \delta b^i \), so the cost incurred by SWITCH during phase \( i \), starting from its position at time \( \ell \), can be bounded as

\[
C_{\text{SWITCH}}(\ell + 1, \bar{\ell}) = \sum_{t = \ell + 1}^{\bar{\ell}} f_t(x_t) + \|x_t - x_{t-1}\|
\]

\[
= f_{\ell+1}(x_{\ell+1}) + \|x_{\ell+1} - x_\ell\| + \sum_{t = \ell + 2}^{\bar{\ell}} f_t(x_t) + \|x_t - x_{t-1}\|
\]

\[
\leq f_{\ell+1}(x_{\ell+1}) + \|x_{\ell+1} - x_0\| + \|x_\ell - x_0\| + \sum_{t = \ell + 2}^{\bar{\ell}} f_t(x_t) + \|x_t - x_{t-1}\|
\]

\[
= f_{\ell+1}(\text{ROB}_{\ell+1}) + \|\text{ROB}_{\ell+1} - x_0\| + \|\text{ADV}_\ell - x_0\|
\]

\[
+ \sum_{t = \ell + 2}^{\bar{\ell}} f_t(\text{ROB}_t) + \|\text{ROB}_t - \text{ROB}_{t-1}\|
\]

\[
\leq C_{\text{ROB}}(1, \bar{\ell}) + C_{\text{ADV}}(1, \ell)
\]

\[
\leq \delta b^i + b^{i-1}.
\]

where the first two bounds use the triangle inequality, and the last bound follows by construction of \( \ell \) and \( \bar{\ell} \). By a very similar argument, if \( i \) is even, we can bound the cost incurred by SWITCH during phase \( i \) as \( \delta b^{i-1} + b^i \). Then the total cost expenditure of SWITCH through the end of some phase \( N > 0 \) is at most

\[
b^0 + \sum_{i=0}^{\left\lfloor \frac{N-1}{2} \right\rfloor} (\delta b^{2i+1} + b^{2i}) + \sum_{j=1}^{\left\lfloor \frac{N}{2} \right\rfloor} (\delta b^{2j-1} + b^{2j})
\]

\[
= \begin{cases} 
  b^N + 2 \sum_{i=0}^{\left\lfloor \frac{N}{2} \right\rfloor} b^{2i} + \delta b^{2i+1} 
  & \text{if } N \text{ is even} \\
  \delta b^N + 2b^{N-1} + 2 \sum_{i=0}^{\left\lfloor \frac{N-2}{2} \right\rfloor} (b^{2i} + \delta b^{2i+1}) 
  & \text{if } N \text{ is odd}
\end{cases}
\]

(1)

Suppose then that the instance ends at time \( T \) during phase \( N \). We break into cases depending on the value of \( N \).
First, if \( N = 0 \), then clearly \( C_{\text{SWITCH}} = C_{\text{ADV}} \), so SWITCH is 1-competitive with respect to ADV. Moreover, since \( C_{\text{ADV}} \leq b^0 = 1 \), then by the assumption in the proposition statement that \( C_{\text{ROB}} \geq 1 \), it follows that SWITCH is at most 1-competitive with respect to ROB.

Second, if \( N = 1 \), then \( C_{\text{SWITCH}} \leq 2b^0 + C_{\text{ROB}} = 2 + C_{\text{ROB}} \). Since \( C_{\text{ADV}} > 1 \) and \( C_{\text{ROB}} \leq \delta b \) (due to the instance ending at phase \( N = 1 \)), this means that SWITCH is at most \( (2 + \delta b) \)-competitive with respect to ADV. Moreover, by assumption \( C_{\text{ROB}} \geq 1 \), SWITCH is at most 3-competitive with respect to ROB.

Next, suppose \( N > 1 \) and \( N \) is even. Then we have

\[
C_{\text{SWITCH}} \leq 2 \sum_{i=0}^{\frac{N}{2}-1} (b^{2i} + \delta b^{2i+1}) + C_{\text{ADV}}
\]

which follows by applying (1) to bound cost through phase \((N - 1)\), and bounding the remaining cost by \( \delta b^{N-1} + C_{\text{ADV}} \), i.e., the cost to switch back to ADV and follow it until the instance ends. Then note that \( C_{\text{ADV}} \geq b^{N-2} \) by definition of phase; introducing the substitution \( 2k := N - 2 \), we find that the competitive ratio of SWITCH with respect to ADV is bounded as

\[
\frac{C_{\text{SWITCH}}}{C_{\text{ADV}}} \leq 1 + 2 \sum_{i=0}^{k} \left( \frac{b^{2i} + \delta b^{2i+1}}{b^{2k}} \right)
\]

\[
= 1 + 2 \left( \frac{b^{2k+2} - 1}{b^{2k}(b^2 - 1)} + \delta b^{2k+2} - 1 \right)
\]

\[
\leq 1 + 2 \left( \frac{b^2}{b^2 - 1} + \frac{\delta b}{b^2 - 1} \right).
\]

On the other hand, we know that \( C_{\text{ADV}} \leq b^N \) and \( C_{\text{ROB}} \geq \delta b^{N-1} \), so by similar reasoning the competitive ratio of SWITCH with respect to ROB is bounded as

\[
\frac{C_{\text{SWITCH}}}{C_{\text{ROB}}} \leq \frac{b}{\delta} + 2 \sum_{i=0}^{k} \left( \frac{b^{2i} + \delta b^{2i+1}}{\delta b^{2k+1}} \right)
\]

\[
\leq \frac{b}{\delta} + 2 \left( \frac{b}{\delta(b^2 - 1)} + \frac{b^2}{b^2 - 1} \right).
\]

Finally, consider \( N > 1 \) for odd \( N \). Then

\[
C_{\text{SWITCH}} \leq 2 \sum_{i=0}^{\frac{N-1}{2}} b^{2i} + \sum_{i=0}^{\frac{N-3}{2}} \delta b^{2i+1} + C_{\text{ROB}}.
\]

Noting that \( C_{\text{ROB}} \leq \delta b^N \), \( C_{\text{ADV}} \geq b^{N-1} \), and making the substitution \( 2k = N - 1 \), we obtain that the competitive ratio of SWITCH with respect to ADV is bounded as

\[
\frac{C_{\text{SWITCH}}}{C_{\text{ADV}}} \leq \delta b + 2 \sum_{i=0}^{k} \frac{b^{2i}}{b^{2k}} + \sum_{i=0}^{k-1} \frac{\delta b^{2i+1}}{b^{2k}}
\]

\[
\leq \delta b + 2 \left( \frac{b^2}{b^2 - 1} + \delta \frac{b}{b^2 - 1} \right).
\]
On the other hand, we know that $C_{\text{ROB}} \geq \delta b^{N-2} = \delta b^{2k-1}$. Thus the competitive ratio of \textsc{Switch} with respect to \textsc{ROB} is bounded as

$$\frac{C_{\text{Switch}}}{C_{\text{ROB}}} \leq 1 + 2 \frac{\sum_{i=0}^{k} b^{2i} + \sum_{i=0}^{k-1} \delta b^{2i+1}}{\delta b^{2k-1}} \leq 1 + 2 \left( \frac{b^3}{b^2 - 1} + \frac{b^2}{b^2 - 1} \right).$$

Combining these various cases, we obtain that \textsc{Switch} is

$$\left( 1 + 2 \left( \frac{b^2}{b^2 - 1} + \delta \frac{b^3}{b^2 - 1} \right) \right), 1 + 2 \left( \frac{b^2}{b^2 - 1} + \frac{1}{\delta} \frac{b^3}{b^2 - 1} \right)$$

$b$-bicompetic with respect to $(\text{Adv}, \text{ROB})$. Introducing an auxiliary parameter $\gamma$ and making the substitutions $\delta \leftarrow b \gamma^2 - b^{-1}, b \leftarrow \sqrt{\gamma^{-2} + 1}$, and $\gamma \leftarrow \sqrt{3}$, we arrive at the bicompetitive bound in terms of $\epsilon$ stated in the proposition. \hfill $\blacksquare$

B.3. Proof of Theorem 8

We consider the setting of $\mathbb{R}^d$ with the $\ell^2$ norm, where the advice $\text{Adv}$ is adversarial and $\text{ROB}$ is an arbitrary $b$-competitive algorithm for CBC, with $b < \infty$; $\text{ALG}$ is any algorithm that switches between $\text{ROB}$ and $\text{Adv}$. For simplicity of presentation, we will assume that $\sqrt{d}$ is an integer. $\text{ROB}$ is assumed to be advice-agnostic, i.e., the behavior of $\text{Adv}$ does not impact the decisions made by $\text{ROB}$ (nor does the behavior of $\text{ALG}$, since $\text{ALG}$ itself depends on both $\text{Adv}$ and $\text{ROB}$). We construct a lower bound in the spirit of the standard example of chasing faces of the hypercube. At a high level, the CBC instance we construct has two phases: the first is comprised of multiple subphases in which an affine subspace is chosen adversarially and is repeatedly served until $\text{ROB}$ has “almost” stopped moving. This phase lasts either until $3 \sqrt{d}$ subphases have concluded, or until the first time that $\text{ALG}$ coincides with $\text{Adv}$ at the end of a subphase, whichever happens sooner. If the former holds, i.e., if $\text{ALG}$ ends each of the $3 \sqrt{d}$ subphases at $\text{ROB}$, then the instance is done. Otherwise, the second phase begins: there are a few different cases, but generally, the same affine subspace is served repeatedly while $\text{Adv}$ slowly drifts away from $\text{ROB}$ until $\text{ALG}$ switches back to $\text{ROB}$. Then, the final body is simply the last advice decision as a singleton, forcing $\text{ALG}$ to move back to the advice, and the instance concludes.

We now describe the lower bound in more specific detail. Since $\text{ROB}$ is advice-agnostic, we may begin by describing its behavior before specifying the behavior of $\text{Adv}$ and reasoning about the switching algorithm $\text{ALG}$. We denote by $e_j \in \mathbb{R}^d$, $j \in [d]$ the $j^{\text{th}}$ standard unit basis vector, which is 1 in its $j^{\text{th}}$ entry and 0 elsewhere. Choose any $\delta > 0$. The starting position is $x_0 = 0$.

Phase one. At time $t = 1$, the served body $K_1$ is the hyperplane forcing the first coordinate to be $z_1 := 1$:

$$K_1 = \left\{ x : x^\top e_1 = z_1 \right\}.$$ 

This same hyperplane $K_1$ is then repeatedly served until the time $m_1$ at which $\text{ROB}$ is almost stationary. That is, the time $m_1 < \infty$ is chosen to satisfy the property that the cumulative cost incurred by $\text{ROB}$ after time $m_1$, if $K_1$ were repeated indefinitely thereafter, is bounded above by $\delta$. Such a time $m_1$ must exist, since $\text{ROB}$ is $b$-competitive, the offline optimal cost for the instance
an incremented value of \( j \) and move on to phase two below. Otherwise, we remain in phase one and repeat this step with \( K \). Note that this forces \( \text{ROB} \) to incur cost at least 1 at time \( m_1 + 1 \). This same body is repeated until the time \( m_2 \) at which \( \text{ROB} \) is almost stationary. That is, just as before, \( m_2 \) is defined as the time at which, if \( K \) were repeated indefinitely from time \( m_2 + 1 \) onward, \( \text{ROB} \) would incur total cost no more than \( \delta \) after time \( m_2 \). For the same reason as before, \( m_2 < \infty \) is certain to exist by \( b \)-competitiveness of \( \text{ROB} \). If \( \text{ALG}_{m_2} = \text{ADV}_{m_2} \), then we say that phase one is complete and move on to phase two below. Otherwise, we continue to the next subphase in phase one as follows.

Let \( z_2 := - \text{sgn}(\text{ROB}_{m_1,2}) \) be the negative of the sign of \( \text{ROB} \)'s second entry at time \( m_1 \) (defaulting to 1 if \( \text{ROB}_{m_1,2} = 0 \)). At time \( t = m_1 + 1 \), we serve a new affine subspace \( K_2 \) defined as

\[
K_2 = \{ x : x^\top e_i = z_i, \ i = 1, 2 \}.
\]

Note that this forces \( \text{ROB} \) to incur cost at least 1 at time \( m_1 + 1 \). This same body is repeated until the time \( m_2 \) at which \( \text{ROB} \) is almost stationary. That is, just as before, \( m_2 \) is defined as the time at which, if \( K_2 \) were repeated indefinitely from time \( m_2 + 1 \) onward, \( \text{ROB} \) would incur total cost no more than \( \delta \) after time \( m_2 \). For the same reason as before, \( m_2 < \infty \) is certain to exist by \( b \)-competitiveness of \( \text{ROB} \). If \( \text{ALG}_{m_2} = \text{ADV}_{m_2} \), then we say that phase one is complete and move on to phase two below. Otherwise, we continue to the next subphase in phase one.

The remaining subphases in phase one are constructed similarly: for each \( j = 3, \ldots, 3\sqrt{d} \), we define \( z_j := - \text{sgn}(\text{ROB}_{m_{j-1},j}) \) to be the negative of the sign of \( \text{ROB} \)'s \( j \)th entry at time \( m_{j-1} \), and at time \( t = m_{j-1} + 1 \), we serve a new affine subspace \( K_j \) defined as

\[
K_j = \{ x : x^\top e_i = z_i, \ i = 1, \ldots, j \},
\]

which forces \( \text{ROB} \) to incur cost at least 1. This body \( K_j \) is then repeated until the time \( m_j \) at which \( \text{ROB} \) is almost stationary, i.e., after which it would incur cumulative cost no more than \( \delta \), were \( K_j \) to be repeated indefinitely. Then, if \( \text{ALG}_{m_j} = \text{ADV}_{m_j} \), we say that phase one is complete and move on to phase two below. Otherwise, we remain in phase one and repeat this step with an incremented value of \( j \). Once the subphase corresponding to \( j = 3\sqrt{d} \) is completed, then the instance is concluded without moving on to phase two.

**Behavior of the advice.** We specify the behavior of \( \text{ADV} \) based on the behavior of \( \text{ROB} \) on the (possibly) counterfactual instance wherein phase one runs to termination without moving to phase two. That is, let \( r_1, r_2, \ldots, r_{3\sqrt{d}} \) be the decisions of \( \text{ROB} \) on an auxiliary CBC instance where \( K_1 \) is served from time 1 through \( m_1 \), \( K_2 \) is served from time \( m_1 + 1 \) through \( m_2 \), and so on, terminating with \( K_{3\sqrt{d}} \) being served from time \( m_{3\sqrt{d}} - 1 \) through \( m_{3\sqrt{d}} \). Then define

\[
a = \arg\max_{x \in \{\pm 1\}^{d-3\sqrt{d}}} \min_{j=1,\ldots,3\sqrt{d}} \| x - r_{m_j,3\sqrt{d}+1} \|_{\ell^2},
\]

where \( r_{m_j,3\sqrt{d}+1} \) is the vector obtained by dropping the first \( 3\sqrt{d} \) entries in \( r_{m_j} \). Thus, \( a \) is the corner of the hypercube \( \{\pm 1\}^{d-3\sqrt{d}} \) that is farthest (in \( \ell^2 \)) from any of the subvectors comprised of the last \( d - 3\sqrt{d} \) entries of the decisions \( r_{m_1}, \ldots, r_{m_{3\sqrt{d}}} \) made by \( \text{ROB} \) at the conclusion of the phase one subphases. Then we define the advice’s phase one behavior simply as follows: at time 1, the advice immediately moves to the point

\[
\hat{a} = (z_1, \ldots, z_{3\sqrt{d}}, a_1, \ldots, a_{d-3\sqrt{d}}),
\]

and it remains there until phase one is completed.

**Phase two.** Fix \( \epsilon > 0 \). Suppose that phase one terminates at time \( m_j \), where \( j < 3\sqrt{d} \) (since if \( j = 3\sqrt{d} \), then the instance ends without moving on to phase two). Thus it is the case that \( \text{ALG}_{m_j} = \text{ADV}_{m_j} = \hat{a} \), and \( \text{ROB}_{m_j} = r_{m_j} \). Then the instance splits into two cases:
1.) Suppose that \( \|a - r_{m_j, 3\sqrt{d} + 1}\| \geq \sqrt{d - 3\sqrt{d}} \), and define \( \mathbf{v} = \frac{a - r_{m_j, 3\sqrt{d} + 1}}{\|a - r_{m_j, 3\sqrt{d} + 1}\|} \). Then at each time \( t = m_j + 1, \ldots, m_j + k \) (where \( k \) will be defined later), we serve the body \( K_j \) again. By our selection of \( m_j \), the robust algorithm \( \text{ROB} \) will remain \( \delta \)-close to its decision \( \text{ROB}_{m_j} \), since we are simply continuing to serve the same body. However, at each of these times, we make the advice move to the point

\[
\text{ADV}_t = \left( z_1, \ldots, z_{3\sqrt{d}}, a_1 + (t - m_j)\ell v_1, \ldots, a_{d - 3\sqrt{d}} + (t - m_j)\ell v_{d - 3\sqrt{d}} \right).
\]

That is, at each time \( t = m_j + 1, \ldots, m_j + k \), the advice takes a step of length \( \epsilon \) in the direction \( \mathbf{v} \) in its last \( d - 3\sqrt{d} \) coordinates. Then \( k \) is chosen such that \( m_j + k \) is the first time after \( m_j \) at which \( \text{ALG}_{m_j + k} = \text{ROB}_{m_j + k} \), i.e., the first time at which the algorithm switches back to \( \text{ROB} \) after following the advice. Note that \( k < \infty \), by the assumption that \( \text{ALG} \) has finite robustness. Then the final body is chosen as

\[
K_{\text{fin}} = \{ \text{ADV}_{m_j + k} \} = \left\{ \left( z_1, \ldots, z_{3\sqrt{d}}, a_1 + k\ell v_1, \ldots, a_{d - 3\sqrt{d}} + k\ell v_{d - 3\sqrt{d}} \right) \right\},
\]
which allows the advice to stay put while \( \text{ROB} \) and \( \text{ALG} \) must move back to coincide with it.

2.) Suppose that \( \|a - r_{m_j, 3\sqrt{d} + 1}\| < \sqrt{d - 3\sqrt{d}} \). Since \( a \) maximizes the objective of (3), then it must hold that

\[
\min_{i = 1, \ldots, 3\sqrt{d}} \|a - r_{m_i, 3\sqrt{d} + 1}\| < \sqrt{d - 3\sqrt{d}}.
\] (4)

Let \( i^* \) be the minimizing index in (4); note that \( i^* \neq j \), since otherwise,

\[
2\sqrt{d - 3\sqrt{d}} = \|2a\|
\leq \|a - r_{m_j, 3\sqrt{d} + 1}\| + \|a + r_{m_j, 3\sqrt{d} + 1}\| < 2\sqrt{d - 3\sqrt{d}}
\]

giving a contradiction. Then the instance splits into two further subcases:

(a) Suppose that \( i^* < j \). Then, just as in case 1.), at each time \( t = m_j + 1, \ldots, m_j + k \), we serve the body \( K_j \) again. At each of these times, we make the advice move to the point

\[
\text{ADV}_t = \left( z_1, \ldots, z_{3\sqrt{d}}, a_1 + (t - m_j)\ell v_1, \ldots, a_{d - 3\sqrt{d}} + (t - m_j)\ell v_{d - 3\sqrt{d}} \right),
\]

where \( \mathbf{v} = \frac{a - r_{m_j, 3\sqrt{d} + 1}}{\|a - r_{m_j, 3\sqrt{d} + 1}\|} \) just as in case 1.). Just as in case 1.), \( k \) is chosen such that \( m_j + k \) is the first time after \( m_j \) at which \( \text{ALG}_{m_j + k} = \text{ROB}_{m_j + k} \), i.e., the first time at which the algorithm switches back to \( \text{ROB} \) after following the advice. Then the final body is chosen as

\[
K_{\text{fin}} = \{ \text{ADV}_{m_j + k} \} = \left\{ \left( z_1, \ldots, z_{3\sqrt{d}}, a_1 + k\ell v_1, \ldots, a_{d - 3\sqrt{d}} + k\ell v_{d - 3\sqrt{d}} \right) \right\},
\]
which allows the advice to stay put while \( \text{ROB} \) and \( \text{ALG} \) must move back to coincide with it.
(b) Suppose that \(i^* > j\). Then for each \(l = j + 1, \ldots, i^*\), serve the body \(K_l\) as defined in (2) from time \(m_{l-1} + 1\) through \(m_l\), while keeping the advice at the same point \(\hat{a}\). Since ROB is advice agnostic this sequence of bodies coincides with the remainder of the phase one sequence of bodies, it will be the case that \(\text{ROB}_{m_{i^*}} = r_{m_{i^*}}\). Then, finally, we split into two further subcases.

(i) If \(\text{ALG}_{m_{i^*}} = \text{ROB}_{m_{i^*}} = r_{m_{i^*}}\), then simply choose the final body as

\[ K_{\text{fin}} = \{ \hat{a} \}, \]

which allows the advice to stay put while ROB and ALG must move back to coincide with it.

(ii) If \(\text{ALG}_{m_{i^*}} = \text{ADV}_{m_{i^*}} = \hat{a}\), then proceed similarly to subcase (a): for each time \(t = m_{i^*} + 1, \ldots, m_{i^*} + k\), serve the body \(K_{i^*}\) again and make the advice move to the point

\[ \text{ADV}_t = \left( z_1, \ldots, z_{3\sqrt{d}}, a_1 + (t - m_j)\epsilon v_1, \ldots, a_{d-3\sqrt{d}} + (t - m_j)\epsilon v_{d-3\sqrt{d}} \right), \]

where this time \(v = \frac{a - r_{m_{i^*}, 3\sqrt{d}+1}}{\|a - r_{m_{i^*}, 3\sqrt{d}+1}\|_2}\). Just as in subcase (a), \(k\) is chosen such that \(m_{i^*} + k\) is the first time after \(m_{i^*}\) at which \(\text{ALG}_{m_{i^*}+k} = \text{ROB}_{m_{i^*}+k}\), i.e., the first time at which the algorithm switches back to ROB after following the advice starting from time \(m_{i^*}\). Then the final body is simply chosen as

\[ K_{\text{fin}} = \{ \text{ADV}_{m_{j+k}} \} = \left\{ \left( z_1, \ldots, z_{3\sqrt{d}}, a_1 + k\epsilon v_1, \ldots, a_{d-3\sqrt{d}} + k\epsilon v_{d-3\sqrt{d}} \right) \right\}, \]

which allows the advice to stay put while forcing ROB and ALG to move to coincide with it.

**Cost analysis.** Let us now tally costs for each of the cases of the instance to prove the result.

Consider the initial case where the instance never makes it out of phase one; this means that \(3\sqrt{d}\) subphases occur in phase one, and ALG finishes each subphase at the ROB decision. Since \(\|r_{m_j} - r_{m_{j-1}}\|_2 \geq 1\) for each \(j = 1, \ldots, 3\sqrt{d}\) (where \(r_{m_0} := r_0 = x_0\)), this means that ALG incurs cost at least \(3\sqrt{d}\), whereas the advice, which moves immediately to \(\hat{a} \in \{ \pm 1 \}^d\) and stays there throughout the entire instance, incurs cost \(\sqrt{d}\). Thus ALG is at least 3-consistent, and we are done.

Now, we turn to each of the cases within which the instance makes it to phase two. First, consider case 1.) Since \(\text{ALG}_{m_j} = \text{ADV}_{m_j} = \hat{a}\), the cost incurred by ALG through time \(m_j\) is at least \(\sqrt{d}\). Then from time \(m_j\) to \(m_j + k - 1\) while ALG is following the advice, ALG incurs cost \(\| (k - 1)\epsilon v \|_2 = (k - 1)\epsilon\). At time \(m_j + k\), ALG switches back to ROB, incurring cost at least

\[
\|\text{ADV}_{m_j+k-1} - \text{ROB}_{m_j+k}\|_2^2 \geq \|\text{ADV}_{m_j+k-1} - \text{ROB}_{m_j}\|_2^2 - \|\text{ROB}_{m_j} - \text{ROB}_{m_j+k}\|_2^2 \\
\geq \|\text{ADV}_{m_j+k-1} - \text{ROB}_{m_j}\|_2^2 - \delta \\
\geq \|\text{ADV}_{m_j+k-1,3\sqrt{d}+1} - \text{ROB}_{m_j,3\sqrt{d}+1}\|_2^2 - \delta \\
= \| (a + (k - 1)\epsilon v) - r_{m_j,3\sqrt{d}+1} \|_2^2 - \delta \\
= \| a - r_{m_j,3\sqrt{d}+1} \|_2^2 + (k - 1)\epsilon - \delta \\
\geq \sqrt{d} - 3\sqrt{d} + (k - 1)\epsilon - \delta. \tag{5}
\]
Finally, by an analogous argument to (5), to switch back to ADV, ALG incurs a cost of at least \( \sqrt{d - 3\sqrt{d} + k\epsilon - \delta} \). In sum, ALG incurs a total cost of \( \sqrt{d + 2\sqrt{d - 3\sqrt{d}} + (3k - 2)\epsilon - 2\delta} \). On the other hand, ADV incurs a total cost of \( \sqrt{d + k\epsilon} \). Then the consistency of ALG is

\[
\frac{\sqrt{d + 2\sqrt{d - 3\sqrt{d}} + (3k - 2)\epsilon - 2\delta}}{\sqrt{d + k\epsilon}}
\]

which can be made arbitrarily close to 3 by choosing \( \epsilon \) and \( \delta \) small and taking \( d \) arbitrarily large.

Next, let's move to case 2.). First, we set up some preliminaries. Let's call \( \rho = \sqrt{d - 3\sqrt{d}} - \|a - r_{m_j,3\sqrt{d}+1}\| \), and note that \( \rho > 0 \). Since \( \|a - r_{m_j,3\sqrt{d}+1}\| \geq \|a - r_{m_j,3\sqrt{d}+1}\| \), we have that

\[
\|a - r_{m_j,3\sqrt{d}+1}\| \geq \sqrt{d - 3\sqrt{d}} - \rho
\]

and hence

\[
\|r_{m_j,3\sqrt{d}+1}\| \geq \|a\| - \|a - r_{m_j,3\sqrt{d}+1}\| \geq \rho
\]

Then

\[
\|a\| - \|a - r_{m_j,3\sqrt{d}+1}\| \geq \|a - r_{m_j,3\sqrt{d}+1}\| \geq \rho
\]

where \( \Pi_K x \) denotes the projection of the point \( x \) onto the convex body \( K \), (8) follows from \( a \) and \( r_{m_j,3\sqrt{d}+1} \) being subvectors of \( a \) and \( r_{m_j,3\sqrt{d}+1} \), respectively, (9) follows from (6) and non-expansivity of the projection, (10) follows from translation, (11) applies the fact that the projection onto an origin-centered ball is just a radial projection, and (12) follows from \( \|a\| \geq \sqrt{d - 3\sqrt{d}} \).

Now, let's consider the subcases, starting with subcase (a). Since \( i^* < j \), we know that \( \text{ALG}_{m_j} = \text{ROB}_{m_j} = r_{m_j} \). Then by (7), ALG incurs cost at least \( \rho \) to get to \( r_{m_j} \), and by (12) it incurs another cost of at least \( \sqrt{d - 3\sqrt{d} + \rho} \) to get to \( \text{ADV}_{m_j} = \hat{a} \). From time \( m_j \) to \( m_j + k - 1 \) while ALG is following the advice, ALG incurs cost \( (k - 1)\epsilon \). Then at time \( m_j + k \), ALG switches back to ROB, and by a similar analysis to that in (5) done for case 1.), it incurs cost at least \( \sqrt{d - 3\sqrt{d} - \rho + (k - 1)\epsilon - \delta} \) to do so. Finally, to switch back to ADV, ALG incurs a cost of at least \( \sqrt{d - 3\sqrt{d} - \rho + k\epsilon - \delta} \). Then in sum, ALG has incurred a total cost of \( 3\sqrt{d - 3\sqrt{d} + (3k - 2)\epsilon - 2\delta} \) in this instance case. On the other hand, ADV incurs a total cost of \( \sqrt{d + k\epsilon} \), so ALG has consistency

\[
\frac{3\sqrt{d - 3\sqrt{d} + (3k - 2)\epsilon - 2\delta}}{\sqrt{d + k\epsilon}}.
\]
which can be made arbitrarily close to 3 by choosing \( \epsilon \) and \( \delta \) small and taking \( d \) arbitrarily large.

Now, we move to subcase (b), beginning first with (i). ALG spends \( \sqrt{d} \) to get to \( \text{ADV}_{m_j} = \mathbf{a} \) in the first place, and then by (12) it spends cost at least \( \sqrt{d - 3\sqrt{d} + \rho} \) to get to \( \text{ROB}_{m_i} \) at time \( m_i \). Finally, it spends at least another \( \sqrt{d - 3\sqrt{d} + \rho} \) to get back to \( \mathbf{a} \) for the final timestep. Thus in sum, ALG incurs cost \( \sqrt{d} + 2(\sqrt{d - 3\sqrt{d} + \rho}) \), whereas ADV incurs cost \( \sqrt{d} \), giving a consistency of

\[
\frac{\sqrt{d} + 2(\sqrt{d - 3\sqrt{d} + \rho})}{\sqrt{d}},
\]

which even for arbitrarily small \( \rho > 0 \) can be made arbitrarily close to 3 by choosing \( d \) sufficiently large.

Finally, we consider scenario (ii) in subcase (b). ALG first spends \( \sqrt{d} \) to get to \( \text{ADV}_{m_j} = \mathbf{a} \), and then from time \( m_i + 1 \) through \( m_i + k - 1 \) it incurs cost \( (k-1)\epsilon \) to follow the advice. Using (12) and reasoning analogous to that in (5), ALG incurs cost \( \sqrt{d - 3\sqrt{d} + \rho} + (k-1)\epsilon - \delta \) to switch back to ROB at time \( m_i + k \), and finally, it incurs cost \( \sqrt{d - 3\sqrt{d} + \rho} + k\epsilon - \delta \) to switch back to the advice in the final timestep. Thus in sum, ALG incurs cost at least \( \sqrt{d} + 2(\sqrt{d - 3\sqrt{d} + \rho}) + (3k-2)\epsilon - 2\delta \), while ADV incurs cost \( \sqrt{d} + k\epsilon \). Thus ALG has consistency

\[
\frac{\sqrt{d} + 2(\sqrt{d - 3\sqrt{d} + \rho}) + (3k-2)\epsilon - 2\delta}{\sqrt{d} + k\epsilon},
\]

which, even for very small \( \rho > 0 \), can be made arbitrarily close to 3 by choosing \( \epsilon, \delta \) small and taking \( d \) sufficiently large.

\[\blacksquare\]

### B.4. Proof of Proposition 9

Let us first recall Theorem 2.1 of Bubeck et al. (2019), which characterizes the cost incurred by moving to the Steiner point of each nested body.

**Theorem 16 (Bubeck et al., 2019, Theorem 2.1)** Let \( x_0 = 0 \) and \( K_1 \subseteq B(0, r) \) for some \( r > 0 \). Then following the Steiner point of each nested body \( K_i \) incurs total movement cost no more than \( rd \).

We now prove Proposition 9. For clarity, we abbreviate \textsc{NestedSwitch} in this proof as NS.

If NS only ever follows ADV, then \( \epsilon \cdot C_{\text{ADV}} < r(d+2) \) and \( C_{\text{NS}} = C_{\text{ADV}} \), so \( C_{\text{NS}} \leq \frac{r(d+2)}{\epsilon} \). Thus NS is 1-competitive with respect to ADV and \( \frac{r(d+2)}{\epsilon} \)-robust, since \( C_{\text{OPT}} \geq 1 \).

On the other hand, if NS only ever follows ROB, then \( C_{\text{NS}} = C_{\text{ROB}} \) and \( \epsilon \cdot C_{\text{ADV}} \geq r(d+2) \). Since ROB just follows the Steiner point of each nested body, we have \( C_{\text{ROB}} \leq r+rd \), where the \( rd \) comes from Theorem 16 and the extra factor of \( r \) arises from the triangle inequality applied to the \( t = 1 \) movement:

\[
\| s_1 - x_0 \|^2 \leq \| s_1 - y \|^2 + \| y - x_0 \|^2 \leq \| s_1 - y \|^2 + r.
\]

Thus \( C_{\text{NS}} = C_{\text{ROB}} \leq r(d+1) \leq (1+\epsilon)C_{\text{ADV}} \), and the desired robustness also holds.
Finally, suppose NS switches to ROB at time $t \in [T]$; i.e., $NS_1 = ADV_1, \ldots, NS_{t-1} = ADV_{t-1}, NS_t = ROB_t, \ldots, NS_T = ROB_T$. We know that

$$C_{NS}(1, t-1) = C_{ADV}(1, t-1) < \frac{r(d+2)}{\epsilon}$$

and since $K_t \subseteq B(y, r)$,

$$C_{NS}(t, t) = \|ROB_t - ADV_{t-1}\|_2 \leq 2r$$

and finally

$$C_{NS}(t+1, T) = C_{ROB}(t+1, T) \leq rd.$$ 

Thus in sum,

$$C_{NS} \leq \frac{r(d+2)}{\epsilon} + rd + 2r = \left(1 + \frac{1}{\epsilon}\right) r(d+2).$$

This gives both the robustness and consistency bounds, since $\epsilon \cdot C_{ADV} \geq r(d+2)$ and $C_{OPT} \geq 1$. 

Appendix C. Background from the geometry of normed vector spaces

In this appendix, we introduce some notions and results from the literature on the geometry of normed vector spaces, expanding on the brief definitions of the rectangular constant and the radial retraction given in the main text in Section 4.1. In the following definitions and results, $\mathcal{X} = (X, \| \cdot \|)$ is an arbitrary real normed vector space.

We begin by defining Birkhoff-James orthogonality, which generalizes the usual Hilbert space orthogonality.

**Definition 17** ((Birkhoff, 1935, p.169); (James, 1947, p.265)) $x \in X$ is Birkhoff-James orthogonal to $y \in X$, denoted $x \perp y$, if $\|x\| \leq \|x + \lambda y\|$ for all $\lambda \in \mathbb{R}$.

Note that, unlike orthogonality in Hilbert spaces, Birkhoff-James orthogonality is not generally symmetric. However, it is homogeneous.

**Lemma 18** ((James, 1947, p.265); (Joly, 1969, Remark 1)) If $x \perp y$, then $ax \perp by$ for all $a, b \in \mathbb{R}$.

Using Birkhoff-James orthogonality, we can formally define the first constant we introduced in Section 4.1: the rectangular constant. It is motivated by the following observation: in a finite-dimensional inner product space, orthogonality of $x$ and $y$ implies that $\|x\| + \|y\| \leq \sqrt{2} \|x+y\|$. In an arbitrary normed vector space, the upper bound $\sqrt{2}$ is replaced with the rectangular constant, defined as follows using Birkhoff-James orthogonality.

**Definition 19** ((Desbiens, 1990, Definition 2); original from (Joly, 1969, Definition 2)) The rectangular constant $\mu(\mathcal{X})$ of a real normed vector space $\mathcal{X}$ is defined as

$$\mu(\mathcal{X}) = \sup_{x \perp y} \frac{\|x\| + \|y\|}{\|x+y\|}.$$
It is known that $\sqrt{2} \leq \mu(\mathcal{X}) \leq 3$ (Joly, 1969, Section II), and these bounds are tight: $\mu(\mathcal{X}) = \sqrt{2}$ for any Hilbert space (Joly, 1969, Example 1; Section III), and $\mu(\mathcal{X}) = 3$ for “nonuniformly nonsquare” spaces such as $\ell^1$ and $\ell^\infty$ (Baronti et al. (2021)). Moreover, $\mu(\ell^p) < 3$ for all $p \in (1, \infty)$. In fact, tighter bounds are known for the $\ell^p$ spaces: we review these in the following theorem.

**Theorem 20 ((Baronti et al., 2021, Theorems 5.2, 5.4, 5.5))** For $1 < p \leq 2$,

$$
\mu(\ell^p) \leq \min \left\{ \left( 1 + \left( 2^{1/(p-1)} - 1 \right)^{p-1} \right)^{1/p}, \sqrt{\frac{p}{p-1}} \right\}.
$$

For $p \geq 2$,

$$
\mu(\ell^p) \leq \left( 1 + \left( 2^{p-1} - 1 \right)^{1/(p-1)} \right)^{(p-1)/p}.
$$

Together, these constitute an upper bound on $\mu(\ell^p)$ that attains a (tight) minimum of $\sqrt{2}$ at $p = 2$, and that continuously increases toward 3 as $p \to \infty$ and $p \to 1$.

We now reiterate the definition of the radial retraction and its Lipschitz constant given in Section 4.1.

**Definition 21 (Rieffel (2006))** On a normed vector space $\mathcal{X} = (X, \| \cdot \|)$, the radial retraction $\rho(\cdot; r) : X \to B(0, r)$ is the metric projection onto the closed ball of radius $r \geq 0$:

$$
\rho(x; r) = \begin{cases} 
  x & \text{if } \|x\| \leq r \\
  \frac{x}{\|x\|} & \text{if } \|x\| > r.
\end{cases}
$$

We define $k(\mathcal{X})$ to be the Lipschitz constant of $\rho(\cdot; 1)$, i.e., the smallest real number satisfying

$$
\|\rho(x; 1) - \rho(y; 1)\| \leq k(\mathcal{X}) \|x - y\|
$$

for all $x, y \in X$.

It holds that $k(\mathcal{X})$ is bounded between 1 and 2 in any normed vector space $\mathcal{X}$ (Thele (1974)). Moreover, $k(\mathcal{X})$ is identically the Lipschitz constant of $\rho(\cdot; r)$ for any $r > 0$ (Rieffel (2006)). To see that this is the case, observe that $\rho(x; r) = r \cdot \rho\left( \frac{x}{r}; 1 \right)$; it then follows that

$$
\|\rho(x; r) - \rho(y; r)\| = r \|\rho\left( \frac{x}{r}; 1 \right) - \rho\left( \frac{y}{r}; 1 \right)\| \leq k(\mathcal{X}) \|x - y\|.
$$

Thus $k(\mathcal{X})$ is an upper bound on the Lipschitz constant of $\rho(x; r)$ for general $r > 0$. Similar reasoning shows that $\rho(x; r)$ can have no smaller Lipschitz constant than $k(\mathcal{X})$; so $k(\mathcal{X})$ is the Lipschitz constant for all $\rho(x; r), r > 0$.

We conclude this section with a result relating $k(\mathcal{X})$ with $\mu(\mathcal{X})$.

**Proposition 22** On a real normed vector space $\mathcal{X} = (X, \| \cdot \|)$, it holds that $k(\mathcal{X}) \leq \mu(\mathcal{X})$.  

30
Proof (Thele, 1974, Theorem 1) characterizes $k(\mathcal{X})$ as follows:

$$k(\mathcal{X}) = \sup_{x \perp y, y \neq 0, \lambda \in \mathbb{R}} \frac{\|y\|}{\|y - \lambda x\|}.$$  \hspace{1cm} (13)

Since, by Lemma 18, Birkhoff-James orthogonality is homogeneous, it is straightforward to see that (13) can be equivalently expressed as

$$k(\mathcal{X}) = \sup_{x \perp y, y \neq 0} \frac{\|y\|}{\|x + y\|}.$$  

Then it is clear that

$$k(\mathcal{X}) = \sup_{x \perp y, y \neq 0} \frac{\|y\|}{\|x + y\|} \leq \sup_{x \perp y} \frac{\|x\| + \|y\|}{\|x + y\|} = \mu(\mathcal{X}).$$

\[\blacksquare\]

Appendix D. Proof of Theorem 11

D.1. Geometric lemmas

Before presenting the analysis of Algorithm 2, we take a brief foray into the geometric theory of normed vector spaces, presenting and proving some lemmas that will be helpful in proving the bi-competitive bound given in Theorem 11. The results in this section depend heavily on the definitions and results introduced in Appendix C.

The first lemma characterizes (a modified form of) the radial retraction as a metric projection onto the boundary of a closed ball.

Lemma 23 Let $(X, \|\cdot\|)$ be a normed vector space, and consider arbitrary $r \geq 0$, $x \in X$, and $y \in X \setminus \{x\}$. Define $\hat{y} = x + r \frac{y - x}{\|y - x\|}$. Then $\|y - \hat{y}\| \leq \|y - w\|$ for all $w \in \partial B(x, r)$.

Proof It suffices to consider the case when $x = 0$. If $r = 0$, $\partial B(0, r) = \{0\}$, so the result is clear. Otherwise, fix arbitrary $w \in \partial B(0, r)$ and observe

$$\|y - w\| \geq \|y\| - \|w\| \hspace{1cm} \text{by the triangle inequality}$$

$$= \|y\| - r$$

$$= \|y\| - \|\hat{y}\|$$

$$= \|y - \hat{y}\|$$

where the last step follows from collinearity of $y$, $\hat{y}$, and $0$. \[\blacksquare\]

The second lemma generalizes the following geometric fact in the Euclidean plane to an arbitrary normed vector spaces: given a triangle $abc$ in $(\mathbb{R}^2, \|\cdot\|_2)$, and points $x \in [a, b], y \in [a, c]$ with $\|x - b\|_2 = \|y - c\|_2$, it holds that $\|x - y\|_2 \leq \|b - c\|_2$. In the general setting, this becomes a statement about the distance between the radial retractions of a single point onto two balls of the same radius with different centers.
Lemma 24  Let \((X, \| \cdot \|)\) be a normed vector space, and fix arbitrary \(a, b, c \in X\) and \(r \geq 0\). Define \(x = b + \rho(a - b; r)\) and \(y = c + \rho(a - c; r)\). Then \(\|x - y\| \leq \|b - c\|\).

**Proof**  We may assume without loss of generality that \(\|a - b\| \geq \|a - c\|\). If \(b = c\), \(\|x - y\| = 0 = \|b - c\|\). Thus we restrict to the case where \(b \neq c\) and distinguish cases based on the value of \(r\). We may further restrict to the case where \(\|a - c\| > 0\), as the case \(a = c\) is trivial.

If \(r = 0\), then \(x = b\) and \(y = c\). Thus \(\|x - y\| = \|b - c\|\). On the other hand, if \(r \geq \|a - b\|\), then \(r \geq \|a - c\|\) as well, so \(x = y = a\), and certainly \(\|x - y\| = 0 \leq \|b - c\|\).

Next, suppose \(\|a - c\| \leq r < \|a - b\|\). Then \(y = a\), so \(\|x - y\| = \|x - a\|\). Moreover, \(\|x - b\| = r \geq \|a - c\|\). Then by the triangle inequality,

\[
\|b - c\| \geq \|a - b\| - \|a - c\| \\
= \|a - x\| + \|x - b\| - \|a - c\| \\
\geq \|a - x\| \\
= \|x - y\|.
\]

Finally, suppose \(0 < r < \|a - c\|\), and define \(\lambda = 1 - \frac{r}{\|a - c\|}\). Since \(y + b - c = b + r \frac{a - c}{\|a - c\|}\), we know that \(y + b - c \in \partial B(b, r)\). Observe moreover that

\[
z := y + \lambda(b - c) = b + r \frac{a - b}{\|a - c\|} \in [a, b]
\]

and \(z \neq b\) by assumption that \(r > 0\). Thus \(\frac{z - b}{z - a} = \frac{a - b}{\|a - c\|}\), so \(x = b + r \frac{z - b}{z - a}\). Thus:

\[
\|b - c\| = \|(y + b - c) - y\| \\
= \| (y + b - c) - z \| + \| z - y \| \quad \text{by collinearity of } y, z, y + b - c \\
\geq \| x - z \| + \| z - y \| \quad \text{applying Lemma 23} \\
\geq \| x - y \| \quad \text{by triangle inequality.}
\]

where, in (14), \(x, y, \hat{y}, w,\) and \(r\) in Lemma 23 are instantiated during its invocation with this proof’s \(b, z, x, (y + b - c),\) and \(r\), respectively.

The next geometric lemma provides a bound on the total distance traveled first between two points on a sphere, and then from the second point to a scaled version thereof, in terms of the rectangular constant and the distance between the initial and final points.

Lemma 25  Let \((X, \| \cdot \|)\) be a normed vector space, and let \(t > 1\), \(r > 0\), and \(x, y \in \partial B(0, r)\). Then

\[
\| y - x \| + (t - 1)\|y\| \leq \mu(X)\|ty - x\|.
\]

**Proof**  By a corollary of the Hahn-Banach theorem (Bollobás, 1999, Chapter 3, Corollary 7), there exists a support functional \(f \in X^*\) at \(y\), i.e., some bounded linear functional \(f : X \to \mathbb{R}\), with \(\|f\|_{X^*} = 1\), \(f(y) = \|y\| = r\), and the property that the hyperplane \(H(r) := \{z \in X : f(z) = r\}\) contains no points in \(\text{int}(B(0, r))\). Note that we can equivalently write \(H(r)\) in affine subspace form \(H(r) = y + \ker(f) = \{z \in X : z = y + h, h \in \ker(f)\}\), by linearity of \(f\). The fact that \(H(r)\) contains no points in the interior of \(B(0, r)\) means that \(y \perp h\) for all \(h \in \ker(f)\).
Define \( s = f(x) \), and note that since \( \|x\| = r \) and \( \|f\|_{X^*} = 1 \), we must have \( s \leq r \). Then define \( z = \frac{s}{r} y \), and observe \( H(s) = x + \ker(f) = z + \ker(f) \). Thus \( x = z + h \) for some specific \( h \in \ker(f) \). By homogeneity of Birkhoff-James orthogonality (Lemma 18), it follows that \((t - \frac{s}{r}) y \perp -h \). As such,

\[
\|y - x\| + (t - 1)\|y\| 
\leq \|y - z\| + \|x - z\| + (t - 1)\|y\|
\]

\[
= \left(1 - \frac{s}{r}\right) \|y\| + \|h\| + (t - 1)\|y\|
\]

\[
= \| - h\| + \left(t - \frac{s}{r}\right) \|y\|
\]

\[
\leq \mu(\mathcal{X}) \left(- h + \left(t - \frac{s}{r}\right) y\right)
\]

\[
= \mu(\mathcal{X}) \|ty - x\|.
\]

Finally, we present a lemma building upon Lemma 25 that will be indispensable for the consistency analysis of Algorithm 2.

**Lemma 26** Let \((X, \| \cdot \|)\) be a normed vector space, and fix arbitrary \( r \geq 0 \), \( w, y \in X \), and \( x \in X \setminus \text{int}(B(w, r)) \). Define \( \hat{x} = w + \rho(x - w; r) \) and \( \hat{y} = w + \rho(y - w; r) \). Then

\[
\|\hat{y} - \hat{x}\| + \|y - \hat{y}\| \leq \mu(\mathcal{X}) \|y - x\| + \|x - \hat{x}\|.
\]

**Proof** If \( r = 0 \), then \( B(w, r) = \{w\} \), so \( \hat{x} = \hat{y} = w \), and the result follows from the triangle inequality, as \( \mu(\mathcal{X}) \geq \sqrt{2} \). Thus we restrict to the case that \( r > 0 \).

It suffices to consider the case where \( w = 0 \). Then \( \hat{x} = \rho(x; r) \) and \( \hat{y} = \rho(y; r) \). We distinguish two cases.

First, suppose \( y \in B(0, r) \). Then \( \hat{y} = y \), and by the triangle inequality,

\[
\|\hat{y} - \hat{x}\| + \|y - \hat{y}\| = \|y - x\| \leq \|y - x\| + \|x - \hat{x}\| \leq \mu(\mathcal{X}) \|y - x\| + \|x - \hat{x}\|.
\]

Second, suppose \( y \in X \setminus B(0, r) \). Then \( \hat{y} = r \frac{y}{\|y\|} \). We distinguish two further subcases.

(i) Suppose that \( \|y - \hat{y}\| \leq \|x - \hat{x}\| \). Then

\[
\|\hat{y} - \hat{x}\| + \|y - \hat{y}\| \leq \|\hat{y} - \hat{x}\| + \|x - \hat{x}\|
\]

\[
\leq \mu(\mathcal{X}) \|y - x\| + \|x - \hat{x}\|
\]

\[
\leq \mu(\mathcal{X}) \|y - x\| + \|x - \hat{x}\| \quad \text{by Proposition 22}.
\]

(ii) On the other hand, suppose that \( \|y - \hat{y}\| > \|x - \hat{x}\| \), or equivalently, \( \|y\| \geq \|x\| \), and define \( z = \rho(y; \|x\|) = \|x\| \frac{y}{\|y\|} \). By collinearity, \( \|z - \hat{y}\| = \|x\| - r = \|x - \hat{x}\| \). Furthermore, we have that

\[
\|\hat{y} - \hat{x}\| \leq \frac{\|x\|}{r} \|\hat{y} - \hat{x}\| = \|z - x\|.
\]
It then follows that
\[
\|\hat{y} - \hat{x}\| + \|y - \hat{y}\| \leq \|z - x\| + \|y - z\| + \|z - \hat{y}\|
\]
\[
= \|z - x\| + \left( \frac{\|y\|}{\|x\|} - 1 \right) \|z\| + \|x - \hat{x}\|
\]
\[
\leq \mu(X) \|y - x\| + \|x - \hat{x}\|
\]
where the final inequality follows from Lemma 25, where \(x, z \in \partial B(0, \|x\|)\) are (respectively) the points \(x, y\) in that lemma’s statement.

We have now presented all technical lemmas that will be employed in our proof of Theorem 11. Before moving on to this proof in the next section, we first provide several immediate corollaries of the preceding lemmas characterizing various steps of Algorithm 2.

**Corollary 27** In the specification of INTERP (Algorithm 2), if \(x_t\) is determined by Line 8, then \(\|x_t - z_t\| \leq \|s_t - s_{t-1}\|\).

**Proof** This follows immediately from Lemma 24 with the lemma’s \(a, b, c, \) and \(r\) respectively chosen as \(\tilde{x}_t, s_{t-1}, s_t\) and \(\|z_t - s_{t-1}\|\).

**Corollary 28** In the specification of INTERP (Algorithm 2),
\[
\|y_t - x_{t-1}\| \leq k(X)\|\tilde{x}_t - \tilde{x}_{t-1}\|.
\]

**Proof** This follows by definition of the Lipschitz constant \(k(X)\) of the radial retraction, and the observation that \(y_t\) (respectively \(x_{t-1}\)) is the radial retraction of \(\tilde{x}_t\) (respectively \(\tilde{x}_{t-1}\)) onto the ball \(B(s_{t-1}, \|x_{t-1} - s_{t-1}\|)\).

**Corollary 29** In the specification of INTERP (Algorithm 2),
\[
\|y_t - x_{t-1}\| + \|\tilde{x}_t - y_t\| \leq \mu(X)\|\tilde{x}_t - \tilde{x}_{t-1}\| + \|\tilde{x}_{t-1} - x_{t-1}\|.
\]

**Proof** This follows immediately from Lemma 26 with \(x, y, w, \) and \(r\) in the lemma’s statement chosen respectively as \(\tilde{x}_{t-1}, \tilde{x}_t, s_{t-1}, \) and \(\|x_{t-1} - s_{t-1}\|\), which in turn yields \(\hat{y} = y_t\) and \(\hat{x} = x_{t-1}\).
D.2. Proof of bicompetitive bound

We prove the bicompetitive bound of Theorem 11 in two parts: we will first show the competitive ratio with respect to ADV, and will follow with the competitive ratio with respect to Rob. Both results proceed via potential function arguments: the first uses the potential function $\|\tilde{x}_t - x_t\|$, and the second uses the potential function $c\|x_t - s_t\|$ (with $c$ to be defined later on). The robustness and consistency claim then follows immediately from the bicompetitive bound and the observation in Appendix A.2.

Proof of competitiveness with respect to ADV. We define “phases” of the algorithm as follows: if $x_t$ is determined by line 4 of the algorithm, then the advice is in the “ADV” phase. Otherwise, if $x_t$ is determined by line 8, then the advice is in the “ROB” phase. We refer to the time indices in which the algorithm is in the “ROB” phase as $R_1, \ldots, R_k \in [T]$ (where $k \leq T$, and $R_1 < \cdots < R_k$ are in increasing order). If the algorithm is never in the “ROB” phase, then $x_t = \tilde{x}_t \forall t \in [T]$, and thus INTERP is 1-competitive with respect to ADV. Thus we restrict to the case that there is at least one time index in which the algorithm is in the “ROB” phase. By design, for each $j \in [k]$, $C_{Rob}(1, R_j) \leq \delta \cdot C_{ADV}(1, R_j)$.

Now we break into two cases depending on the phase. First, suppose that INTERP is in the “ADV” phase. This means that $x_t = \tilde{x}_t$. Then

$$f_t(x_t) + \|x_t - x_{t-1}\| + \|\tilde{x}_t - x_t\| = f_t(\tilde{x}_t) + \|\tilde{x}_t - x_{t-1}\|$$

$$\leq f_t(\tilde{x}_t) + \|\tilde{x}_t - \tilde{x}_{t-1}\| + \|\tilde{x}_{t-1} - x_{t-1}\| \quad (15)$$

follows immediately from the triangle inequality.

Second, consider the case that the algorithm is in the “ROB” phase. This means that $x_t$ is determined by line 8 of the algorithm; and there exists some $\lambda \in [0, 1]$ for which $x_t = \lambda s_t + (1 - \lambda)\tilde{x}_t$. In this case, observe

$$f_t(x_t) + \|x_t - x_{t-1}\| + \|\tilde{x}_t - x_t\|$$

$$\leq \lambda f_t(s_t) + (1 - \lambda)f_t(\tilde{x}_t) + 2\|x_t - z_t\| + 2\|z_t - y_t\| + \|y_t - x_{t-1}\| + \|\tilde{x}_t - y_t\| \quad (16)$$

$$\leq 2 \cdot C_{Rob}(t, t) + 2\gamma \cdot C_{ADV}(t, t) + f_t(\tilde{x}_t) + \|y_t - x_{t-1}\| + \|\tilde{x}_t - y_t\| \quad (17)$$

where (16) follows from convexity of $f_t$ and the triangle inequality, and (17) follows from bounding $\|x_t - z_t\|$ via Corollary 27 and $\|z_t - y_t\|$ via line (7) of the algorithm. Invoking Corollary 29 gives the result

$$f_t(x_t) + \|x_t - x_{t-1}\| + \|\tilde{x}_t - x_t\|$$

$$\leq 2 \cdot C_{Rob}(t, t) + 2\gamma \cdot C_{ADV}(t, t) + f_t(\tilde{x}_t) + \mu(\mathcal{X})\|\tilde{x}_t - \tilde{x}_{t-1}\| + \|\tilde{x}_{t-1} - x_{t-1}\|$$

$$\leq 2 \cdot C_{Rob}(t, t) + (\mu(\mathcal{X}) + 2\gamma)C_{ADV}(t, t) + \|\tilde{x}_{t-1} - x_{t-1}\| \quad (18)$$
Summing (15) and (18) over time and noting that the left-hand side \(\|\tilde{x}_t - x_t\|\) and right-hand side \(\|\tilde{x}_{t-1} - x_{t-1}\|\) telescope, we obtain
\[
C_{\text{INTERP}}(1, T)
\leq \sum_{t=1}^{T} f_t(x_t) + \|x_t - x_{t-1}\| + \|\tilde{x}_t - x_T\|
\leq \sum_{t \in \{R_j\}_{j=1}^{k}} 2 \cdot C_{\text{ROB}}(t, t) + (\mu(\mathcal{X}) + 2\gamma)C_{\text{ADV}}(t, t) + \sum_{t \in [T] \setminus \{R_j\}_{j=1}^{k}} C_{\text{ADV}}(t, t)
\leq 2 \cdot C_{\text{ROB}}(1, R_k) + (\mu(\mathcal{X}) + 2\gamma)C_{\text{ADV}}(1, T)
\leq 2\delta \cdot C_{\text{Adv}}(1, R_k) + (\mu(\mathcal{X}) + 2\gamma)C_{\text{ADV}}(1, T)
\leq (\mu(\mathcal{X}) + \epsilon)C_{\text{ADV}}(1, T)
\]
where the second to last inequality follows from the assumption that the algorithm is in the “ROB” phase at time \(R_k\), implying \(C_{\text{ROB}}(1, R_k) \leq \delta \cdot C_{\text{ADV}}(1, R_k)\); and in the last inequality we use the assumption on the parameters that \(2\gamma + 2\delta = \epsilon\). This gives the competitive bound with respect to \(\text{ADV}\). Note that we can repeat the same argument with truncated time horizon to obtain that \(\text{INTERP}\) is \((\mu(\mathcal{X}) + \epsilon)\)-competitive with respect to \(\text{ADV}\) at every timestep.

**Proof of competitiveness with respect to ROB.** Define the potential function \(\phi_t = c\|x_t - s_t\|\), with \(c > 0\) to be determined later.

Let \(t' \in \{0, \ldots, T\}\) be the last time interval in which the algorithm’s decision is determined by line 4 of the algorithm, or equivalently, the greatest \(t\) such that \(C_{\text{ROB}}(1, t) \geq \delta \cdot C_{\text{ADV}}(1, t)\). Applying the competitive bound of \(\text{INTERP}\) with respect to \(\text{ADV}\) to the subhorizon \(t = 1, \ldots, t'\), we have \(C_{\text{INTERP}}(1, t') \leq (\mu(\mathcal{X}) + \epsilon)C_{\text{ADV}}(1, t')\). By the triangle inequality, and since all algorithms begin at the same starting point \(x_0\), we have \(\|\tilde{x}_{t'} - s_{t'}\| \leq C_{\text{ADV}}(1, t') \leq C_{\text{ROB}}(1, t')\). Putting these together, we have
\[
C_{\text{INTERP}}(1, t') + \phi_{t'} = C_{\text{INTERP}}(1, t') + c\|\tilde{x}_{t'} - s_{t'}\|
\leq (\mu(\mathcal{X}) + \epsilon)C_{\text{ADV}}(1, t') + c(C_{\text{ADV}}(1, t') + C_{\text{ROB}}(1, t'))
\leq \left(\frac{\mu(\mathcal{X}) + \epsilon + c}{\delta}\right) + c)C_{\text{ROB}}(1, t')
\]

Now consider arbitrary \(t \in \{t' + 1, \ldots, T\}\). We distinguish two cases. First, suppose \(x_t = s_t\). Then
\[
f_t(x_t) + \|x_t - x_{t-1}\| + \phi_t - \phi_{t-1} = f_t(s_t) + \|s_t - x_{t-1}\| + c\|s_t - s_{t-1}\| - c\|s_{t-1} - x_{t-1}\|
\leq f_t(s_t) + \|s_t - s_{t-1}\| + \|s_{t-1} - x_{t-1}\| - c\|s_{t-1} - x_{t-1}\|
\leq C_{\text{ROB}}(t, t)
\]
where the final inequality holds so long as \(c \geq 1\).

On the other hand, suppose \(x_t \neq s_t\). Observe that
\[
\|x_t - s_t\| \leq \|z_t - s_{t-1}\| \quad \text{by line 8 of the algorithm}
= \|y_t - s_{t-1}\| - \gamma \cdot C_{\text{Adv}}(t, t) \quad \text{by line 7 of the algorithm and } x_t \neq s_t
\leq \|x_{t-1} - s_{t-1}\| - \gamma \cdot C_{\text{Adv}}(t, t) \quad \text{by line 6 of the algorithm}
\]

(21)
Then noting that \( x_t = \lambda s_t + (1 - \lambda) \tilde{x}_t \) for some \( \lambda \in [0, 1] \), we have

\[
f_t(x_t) + \|x_t - x_{t-1}\| + \phi_t - \phi_{t-1} \leq \lambda f_t(s_t) + (1 - \lambda)f_t(\tilde{x}_t) + \|x_t - x_{t-1}\| - c\gamma \cdot C_{\text{ADV}}(t, t) \tag{22}
\]

\[
f_t(s_t) + f_t(\tilde{x}_t) + \|x_t - z_t\| + \|z_t - y_t\| + \|y_t - x_{t-1}\| - c\gamma \cdot C_{\text{ADV}}(t, t) \leq C_{\text{ROB}}(t, t) + f_t(\tilde{x}_t) + \gamma \cdot C_{\text{ADV}}(t, t) + \|y_t - x_{t-1}\| - c\gamma \cdot C_{\text{ADV}}(t, t) \tag{23}
\]

\[
C_{\text{ROB}}(t, t) + (k(\mathcal{X}) + \gamma - c\gamma)C_{\text{ADV}}(t, t) \leq C_{\text{ROB}}(t, t) + \frac{1 + k(\mathcal{X})}{\gamma} \tag{24}
\]

\[
C_{\text{ROB}}(1, T) \leq \left( 1 + \frac{k(\mathcal{X})}{\gamma} + \frac{\mu(\mathcal{X}) + \epsilon + 1 + \frac{k(\mathcal{X})}{\gamma}}{\delta} \right) C_{\text{ROB}}(1, t') + C_{\text{ROB}}(t' + 1, T)
\]

\[
\leq \left( 1 + \frac{k(\mathcal{X})}{\gamma} + \frac{\mu(\mathcal{X}) + \epsilon + 1 + \frac{k(\mathcal{X})}{\gamma}}{\delta} \right) C_{\text{ROB}}(1, T).
\]

D.3. Parameter optimization

We conclude with a brief comment on the optimal selection of parameters \( \gamma, \delta \) for \text{INTERP}. If we minimize the competitive bound of \text{INTERP} with respect to \text{ROB} over parameters \( \gamma, \delta > 0 \) satisfying \( 2\gamma + 2\delta = \epsilon \), then we obtain the following \( \mathcal{O}(\frac{1}{\gamma}) \) bound on the competitive ratio with respect to \text{ROB} (with arguments of \( \mu(\mathcal{X}), k(\mathcal{X}) \) suppressed):

\[
3 + \frac{2(\epsilon + k(\mathcal{X})(4 + \epsilon + \epsilon \mu(\mathcal{X}))) + 4\sqrt{k(\mathcal{X})(2 + \epsilon)(2k(\mathcal{X}) + \epsilon(1 + \epsilon + \mu(\mathcal{X})))}{\epsilon^2}
\]

which is obtained by setting

\[
\gamma = \sqrt{k(\mathcal{X})(2 + \epsilon)(2k(\mathcal{X}) + \epsilon(1 + \epsilon + \mu(\mathcal{X})))} - k(\mathcal{X})(2 + \epsilon)
\]

\[
2(1 - k(\mathcal{X}) + \epsilon + \mu(\mathcal{X}))
\]

and

\[
\delta = \frac{\epsilon}{2} - \gamma.
\]

With parameters chosen optimally thus, \text{INTERP} is \( (\mu(\mathcal{X}) + \epsilon, \mathcal{O}(\epsilon^{-2})) \)-bicompetitive. Moreover, even if \( \mu(\mathcal{X}) \) and \( k(\mathcal{X}) \) are not known exactly, simply setting \( \gamma = \delta = \frac{\epsilon}{2} \) gives an (up to a constant factor) identical \( (\mu(\mathcal{X}) + \epsilon, \mathcal{O}(\epsilon^{-2})) \)-bicompetitiveness.
Appendix E. Proof of Theorem 12

We prove Theorem 12 in two parts: we first prove the competitive ratio of BDINTERP with respect to ADV, and then we prove the competitive ratio with respect to ROB. The robustness and consistency claim then follows immediately from the bicompetitive bound and the observation in Appendix A.2.

Proof of competitiveness with respect to ADV. We define “phases” of the algorithm as follows: if \( x_t \) is determined by line 4 of the algorithm, then the advice is in the “ADV” phase. Otherwise, if \( x_t \) is determined by line 8, then the advice is in the “ROB” phase. We refer to the time indices in which the algorithm is in the “ROB” phase as \( R_1, \ldots, R_k \in [T] \) (where \( k \leq T \), and \( R_1 < \cdots < R_k \) are in increasing order). If the algorithm is never in the “ROB” phase, then \( x_t = \text{ADV}_t \forall t \in [T] \), and thus BDINTERP is 1-competitive with respect to ADV. Thus we restrict to the case that there is at least one time index in which the algorithm is in the “ROB” phase. By design, for each \( j \in [k] \), \( C_{\text{ROB}}(1, R_j) \leq \delta \cdot C_{\text{ADV}}(1, R_j) \).

Now we break into two cases depending on the phase. First, suppose the BDINTERP is in the “ADV” phase. This means that \( x_t = \tilde{x}_t \). Then

\[
\begin{align*}
& f_t(x_t) + \|x_t - x_{t-1}\| + \|\tilde{x}_t - x_t\| = f_t(\tilde{x}_t) + \|\tilde{x}_t - x_{t-1}\| \\
& \leq f_t(\tilde{x}_t) + \|\tilde{x}_t - x_{t-1}\| + \|\tilde{x}_{t-1} - x_{t-1}\| \tag{27}
\end{align*}
\]

follows immediately from the triangle inequality.

Second, consider the case that the algorithm is in the “ROB” phase. This means that \( x_t \) is determined by line 8 of the algorithm; and there exists some \( \lambda \in [0, 1] \) for which \( x_t = \lambda s_t + (1 - \lambda)\tilde{x}_t \). In this case, observe

\[
\begin{align*}
& f_t(x_t) + \|x_t - x_{t-1}\| + \|\tilde{x}_t - x_t\| \\
& \leq \lambda f_t(s_t) + (1 - \lambda) f_t(\tilde{x}_t) + 2\|x_t - y_t\| + \|y_t - x_{t-1}\| + \|\tilde{x}_t - y_t\| \tag{28} \\
& \leq f_t(s_t) + f_t(\tilde{x}_t) + 2\gamma \cdot C_{\text{ADV}}(t, t) + \|y_t - x_{t-1}\| + \|\tilde{x}_t - y_t\| \tag{29}
\end{align*}
\]

where (28) follows from convexity of \( f_t \) and the triangle inequality, (29) follows via algorithm line 8. Observing that \( x_{t-1} = \nu \tilde{x}_{t-1} + (1 - \nu)s_{t-1} \), we can use the triangle inequality to obtain

\[
\|y_t - x_{t-1}\| \leq \nu \|\tilde{x}_t - \tilde{x}_{t-1}\| + (1 - \nu)\|s_t - s_{t-1}\|. \tag{30}
\]

Moreover, observe

\[
\|\tilde{x}_t - y_t\| = (1 - \nu)\|\tilde{x}_t - s_t\| \\
\leq (1 - \nu)(\|\tilde{x}_t - \tilde{x}_{t-1}\| + \|\tilde{x}_{t-1} - s_{t-1}\| + \|s_t - s_{t-1}\|) \\
= (1 - \nu)(\|\tilde{x}_t - \tilde{x}_{t-1}\| + \|s_t - s_{t-1}\| + \|\tilde{x}_{t-1} - x_{t-1}\|) \tag{31}
\]

where the final equality follows by definition of \( \nu \). Applying (30) and (31) to (29), we obtain

\[
\begin{align*}
& f_t(x_t) + \|x_t - x_{t-1}\| + \|\tilde{x}_t - x_t\| \\
& \leq 2 \cdot C_{\text{ROB}}(t, t) + (1 + 2\gamma)C_{\text{ADV}}(t, t) + \|\tilde{x}_{t-1} - x_{t-1}\| \tag{32}
\end{align*}
\]
Summing (27) and (32) over time and noting that the left-hand side $\|\tilde{x}_t - x_t\|$ and right-hand side $\|\tilde{x}_{t-1} - x_{t-1}\|$ telescope, we obtain

$$
C_{\text{BDINTERP}}(1, T) \\
\leq \sum_{t=1}^{T} f_t(x_t) + \|x_t - x_{t-1}\| + \|\tilde{x}_t - x_T\| \\
\leq \sum_{t \in (R_j)^k \cup (T \setminus \bigcup R_j)^k} 2 \cdot C_{\text{ROB}}(t, t) + (1 + 2\gamma)C_{\text{ADV}}(t, t) + \sum_{t \in (T \setminus \bigcup R_j)^k} C_{\text{ADV}}(t, t) \\
\leq 2 \cdot C_{\text{ROB}}(1, R_k) + (1 + 2\gamma)C_{\text{ADV}}(1, T) \\
\leq 2\delta \cdot C_{\text{ADV}}(1, R_k) + (1 + 2\gamma)C_{\text{ADV}}(1, T) \\
\leq (1 + \epsilon)C_{\text{ADV}}(1, T)
$$

where the second to last inequality follows from the assumption that the algorithm is in the “ROB” phase at time $R_k$, implying $C_{\text{ROB}}(1, R_k) \leq \delta \cdot C_{\text{ADV}}(1, R_k)$; and in the last inequality we use the assumption on the parameters that $2\gamma + 2\delta = \epsilon$. This gives the competitive bound with respect to ADV. Note that we can repeat the same argument with truncated time horizon to obtain that BDINTERP is $(1 + \epsilon)$-competitive with respect to ADV at every timestep.

Proof of competitiveness with respect to ROB. Define the potential function $\phi_t = c \frac{\|x_t - s_t\|}{\|x_t - \tilde{s}_t\|}$, with $c > 0$ to be determined later (we set $\phi_t := 0$ in the case that $\tilde{x}_t = s_t$).

Let $t' \in \{0, \ldots, T\}$ be the last time interval in which the algorithm’s decision is determined by line 4 of the algorithm, or equivalently, the greatest $t$ such that $C_{\text{ROB}}(1, t) \geq \delta \cdot C_{\text{ADV}}(1, t)$. Applying the competitive bound of BDINTERP with respect to ADV to the subhorizon $t = 1, \ldots, t'$, we have $C_{\text{BDINTERP}}(1, t') \leq (1 + \epsilon)C_{\text{ADV}}(1, t')$. Thereby we obtain

$$
C_{\text{BDINTERP}}(1, t') + \phi_{t'} \leq (1 + \epsilon)C_{\text{ADV}}(1, t') + c \\
\leq \frac{1 + \epsilon}{\delta} C_{\text{ROB}}(1, t') + c.
$$

(33)

where in the first inequality we have used the fact that $\|x_t - s_t\| \leq \|\tilde{x}_t - s_t\|$ for all $t$.

Now consider arbitrary $t \in \{t' + 1, \ldots, T\}$. We distinguish two cases. First, suppose $x_t = s_t$ and $\tilde{x}_{t-1} \neq s_{t-1}$. Then

$$
f_t(x_t) + \|x_t - x_{t-1}\| + \phi_t - \phi_{t-1} = f_t(s_t) + \|s_t - x_{t-1}\| - c \frac{\|x_{t-1} - s_{t-1}\|}{\|\tilde{x}_{t-1} - s_{t-1}\|} \\
\leq f_t(s_t) + \|s_t - s_{t-1}\| + \|x_{t-1} - s_{t-1}\| - c \frac{\|x_{t-1} - s_{t-1}\|}{\|\tilde{x}_{t-1} - s_{t-1}\|} \\
\leq C_{\text{ROB}}(t, t)
$$

(34)

where the final inequality holds so long as $c \geq D$, by $D$-boundedness of ADV and ROB. Clearly (34) will also hold in the case that $\tilde{x}_{t-1} = s_{t-1}$, since this will imply $x_{t-1} = s_{t-1}$.

39
On the other hand, suppose \( x_t \neq s_t \). Thus we can assume that \( \tilde{x}_t \neq s_t \) and \( \tilde{x}_{t-1} \neq s_{t-1} \). First, note that

\[
\frac{\|x_t - s_t\|}{\|\tilde{x}_t - s_t\|} = \frac{\|y_t - s_t\| - \gamma \cdot C_{\text{ADV}}(t, t)}{\|\tilde{x}_t - s_t\|} = \nu - \frac{\gamma \cdot C_{\text{ADV}}(t, t)}{\|\tilde{x}_t - s_t\|}
\]

\[
\leq \frac{\|x_{t-1} - s_{t-1}\|}{\|\tilde{x}_{t-1} - s_{t-1}\|} - \frac{\gamma \cdot C_{\text{ADV}}(t, t)}{D}
\]

where (35) follows from line 8 of the algorithm and \( x_t \neq s_t \), and (36) follows by definition of \( \nu \) and the \( D \)-boundedness of \( \text{ADV}, \text{ROB} \).

Then noting that by convexity, \( x_t = \lambda s_t + (1 - \lambda) \tilde{x}_t \) for some \( \lambda \in [0, 1] \), we have

\[
f_t(x_t) + \|x_t - x_{t-1}\| + \phi_t - \phi_{t-1}
\]

\[
\leq \lambda f_t(s_t) + (1 - \lambda) f_t(\tilde{x}_t) + \|x_t - x_{t-1}\| - c\gamma \cdot \frac{C_{\text{ADV}}(t, t)}{D}
\]

\[
\leq f_t(s_t) + f_t(\tilde{x}_t) + \|x_t - y_t\| + \|y_t - x_{t-1}\| - c\gamma \cdot \frac{C_{\text{ADV}}(t, t)}{D}
\]

\[
\leq f_t(s_t) + f_t(\tilde{x}_t) + \gamma \cdot C_{\text{ADV}}(t, t) + \nu \|\tilde{x}_t - \tilde{x}_{t-1}\| + (1 - \nu)\|s_t - s_{t-1}\| - c\gamma \cdot \frac{C_{\text{ADV}}(t, t)}{D}
\]

\[
\leq C_{\text{ROB}}(t, t) + \left(1 + \gamma - \frac{c\gamma}{D}\right) C_{\text{ADV}}(t, t)
\]

\[
\leq C_{\text{ROB}}(t, t)
\]

where (37) follows from convexity and (36), (38) follows from the triangle inequality, and (39) follows from (30) and line 8 of the algorithm. The final inequality (40) holds as long as \( c \geq D + \frac{D}{\gamma} \).

Thus we set \( c = D + \frac{D}{\gamma} \), summing (34) and (40) over times \( t' + 1, \ldots, T \) and adding to (33), we obtain

\[
C_{\text{INTERP}}(1, T) \leq \frac{1 + \epsilon}{\delta} C_{\text{ROB}}(1, t') + D + \frac{D}{\gamma} + C_{\text{ROB}}(t' + 1, T)
\]

\[
\leq \frac{1 + \epsilon}{\delta} C_{\text{ROB}}(1, T) + D + \frac{D}{\gamma}
\]

\[
\leq \left(D + \frac{D}{\gamma} + \frac{1 + \epsilon}{\delta}\right) C_{\text{ROB}}(1, T)
\]

where in the final inequality we have used the assumption that \( C_{\text{ROB}} \geq 1 \).

### E.1. Parameter optimization

To conclude, we briefly comment on the optimal selection of parameters \( \gamma, \delta \) for \text{BDINTERP}. Optimizing the competitive bound of \text{BDINTERP} with respect to \text{ROB} over those \( \gamma, \delta > 0 \) satisfying \( 2\gamma + 2\delta = \epsilon \), we obtain the following \( O\left(\frac{D}{\epsilon}\right) \)-competitive bound with respect to \text{ROB}:

\[
2 + D + \frac{2(1 + D) + 4\sqrt{D(1 + \epsilon)}}{\epsilon}
\]

40
which is obtained by setting
\[ \gamma = \frac{D\epsilon}{2(D + \sqrt{D(1 + \epsilon)})} \]
and
\[ \delta = \frac{\epsilon}{2} - \gamma. \]
With parameters chosen optimally thus, BDINTERP is \((1 + \epsilon, \mathcal{O}(D\epsilon^{-1}))\)-bicompetitive. Moreover, even if \(D\) is not known exactly \(a\) priori, simply setting \(\gamma = \delta = \frac{\epsilon}{4}\) gives an (up to a constant factor) identical \((1 + \epsilon, \mathcal{O}(D\epsilon^{-1}))\)-bicompetitiveness.

**Appendix F. Robustness and consistency corollaries of Theorems 11 and 12**

In this section, we detail the upper bounds on robustness and consistency resulting from Theorems 11 and 12 on CFC and each of its subclasses defined in Appendix A.1. Each of these corollaries follows immediately upon instantiating the robust algorithm ROB provided as input to INTERP (Algorithm 2) or BDINTERP (Algorithm 3) with a competitive algorithm whose competitive ratio is listed in Table 2. We begin with the corollaries of Theorem 11.

**Corollary 30**

(i) INTERP (Algorithm 2) with ROB chosen as the functional Steiner point algorithm (Sellke (2020)) is \((\mu(R^d, \| \cdot \|) + \epsilon)\)-consistent and \(\mathcal{O}(\frac{D}{\epsilon^2})\)-robust for CFC and CBC on \(R^d\) with any norm.

(ii) INTERP (Algorithm 2) with ROB chosen as the low-dimensional chasing algorithm of Argue et al. (2020) is \((\sqrt{2} + \epsilon)\)-consistent and \(\mathcal{O}(\frac{D}{\epsilon^2})\)-robust for \(k\)CBC on \((R^d, \| \cdot \|_{\ell^2})\).

(iii) INTERP (Algorithm 2) with ROB chosen as the greedy algorithm (Zhang et al. (2021)) is \((\mu(X) + \epsilon)\)-consistent and \(\mathcal{O}(\frac{1}{\alpha\epsilon^2})\)-robust for \(\alpha\)CFC on any normed vector space \(X\).

(iv) INTERP (Algorithm 2) with ROB chosen as the greedy OBD algorithm (Lin (2022)) is \((\sqrt{2} + \epsilon)\)-consistent and \(\mathcal{O}(\frac{1}{\epsilon^2})\)-robust for \(\alpha\)CFC on \((R^d, \| \cdot \|_{\ell^2})\).

(v) INTERP (Algorithm 2) with ROB chosen as the Move towards Minimizer algorithm (Argue et al. (2020)) is \((\sqrt{2} + \epsilon)\)-consistent and \(\mathcal{O}(\frac{1}{\epsilon^2})\)-robust for \(k\)CBC on \((R^d, \| \cdot \|_{\ell^2})\).

In particular, each of the consistency bounds is \(\sqrt{2} + \epsilon\) in the case that the decision space is Hilbert.

We now present the corollaries of Theorem 12.

**Corollary 31** In each of the following, suppose that \((\text{ADV, ROB})\) are \(D\)-bounded and \(C_{\text{ROB}} \geq 1\).

(i) BDINTERP (Algorithm 3) with ROB chosen as the functional Steiner point algorithm (Sellke (2020)) is \((1 + \epsilon)\)-consistent and \(\mathcal{O}(\frac{D}{\epsilon^2})\)-robust for CFC and CBC on \(R^d\) with any norm.

(ii) BDINTERP (Algorithm 3) with ROB chosen as the low-dimensional chasing algorithm of Argue et al. (2020) is \((1 + \epsilon)\)-consistent and \(\mathcal{O}(\frac{D}{\epsilon^2})\)-robust for \(k\)CBC on \((R^d, \| \cdot \|_{\ell^2})\).

(iii) BDINTERP (Algorithm 3) with ROB chosen as the greedy algorithm (Zhang et al. (2021)) is \((1 + \epsilon)\)-consistent and \(\mathcal{O}(\frac{D}{\alpha\epsilon})\)-robust for \(\alpha\)CFC on any normed vector space.
(iv) **BdInterp (Algorithm 3)** with **Rob** chosen as the Greedy OBD algorithm (Lin (2022)) is $(1 + \epsilon)$-consistent and $\mathcal{O}(\frac{D}{\alpha^{1/2}\epsilon})$-robust for $\alpha$CFC on $(\mathbb{R}^d, \| \cdot \|_2)$.

(v) **BdInterp (Algorithm 3)** with **Rob** chosen as the Move towards Minimizer algorithm (Argue et al. (2020)) is $(1 + \epsilon)$-consistent and $\mathcal{O}(\frac{2^{\gamma/2}\kappa D}{\epsilon})$-robust for $(\kappa, \gamma)$CFC on $(\mathbb{R}^d, \| \cdot \|_2)$.
