

# MonoNeRF: Learning Generalizable NeRFs from Monocular Videos without Camera Poses

Yang Fu<sup>1</sup> Ishan Misra<sup>2</sup> Xiaolong Wang<sup>1</sup>

Figure 1: We learn a MonoNeRF from monocular videos that can be applied to **depth estimation**, **novel view synthesis**, and **camera pose estimation**.

## Abstract

We propose a generalizable neural radiance fields - *MonoNeRF*, that can be trained on large-scale monocular videos of moving in static scenes without any ground-truth annotations of depth and camera poses. *MonoNeRF* follows an Autoencoder-based architecture, where the encoder estimates the monocular depth and the camera pose, and the decoder constructs a Multiplane NeRF representation based on the depth encoder feature, and renders the input frames with the estimated camera. The learning is supervised by the reconstruction error. Once the model is learned, it can be applied to multiple applications including depth estimation, camera pose estimation, and single-image novel view synthesis. More qualitative results are available at: <https://oasisyang.github.io/mononerf>.

## 1. Introduction

The Neural Radiance Fields (NeRF) have been successfully applied in many applications on not just view synthesis (Mildenhall et al., 2020; Martin-Brualla et al., 2021), but also scene and object reconstruction (Wang et al., 2021a; Yariv et al., 2021; Zhang et al., 2021), semantic understanding (Zhi et al., 2021) and robotics (Li et al., 2022; Simeonov et al., 2022). While these results are encouraging, constructing NeRF requires accurate ground-truth camera poses and the learned NeRF is specific to only one scene in most cases. This usually takes a significant amount of time for training and it also limits the applications in large-scale unconstrained videos.

To accelerate the optimization process of NeRF, more recent focus has been spent on learning generalizable NeRF (Yu et al., 2021; Li et al., 2021; Chen et al., 2021) which is first trained on a dataset with multiple scenes, and then fine-tuned on each individual scene. The learning of a generalizable representation provides a prior that not only accelerates the

optimization (i.e., fine-tuning) process, but also allows reconstruction and view synthesis with only a few view inputs instead of using dense views. However, all these approaches still require training on datasets with given camera poses. While there are also studies on training NeRF without camera poses (Wang et al., 2021c;d), all these efforts are focused on training a NeRF on a single scene instead of generalizing across scenes. One fundamental reason behind this is: it is very challenging to perform calibrations across scenes in a self-supervised way.

In this paper, we propose a novel generalization NeRF called *MonoNeRF*, which can be learnt from monocular videos of moving in static scenes without using any camera ground truths. Our key insight is that, real-world videos often come with slow camera changes (continuity) instead of presenting diverse viewpoints. With this observation, we propose to train an Autoencoder-based model on large-scale real-world videos. Given the input video frames, our framework uses a depth encoder to perform monocular depth estimation for each frame (which is encouraged to be consistent), and a camera pose encoder to estimate the relative camera pose between every two consecutive frames. The **depth encoder feature** and the **camera pose** are the intermediate disentangled representations. For each input frame, we construct a NeRF representation with the depth encoder feature and render it to decode another input frame based on the estimated camera pose. We train the model with the reconstruction loss between the rendered frames and the input frames. However, using a reconstruction loss alone can easily lead to a trivial solution as the estimated monocular depth, camera pose, and the NeRF representation are not necessarily on the same scale. One **key technical contribution** we propose is a novel scale calibration method during training to align these three representations. The advantages of our framework are: (i) Unlike NeRF, it does not need 3D camera pose annotations (e.g., computed via SfM); (ii) It generalizes training on a large-scale video dataset, which leads to better transfer.

At test time, the learned representations can be applied to multiple downstream tasks including: (i) monocular depth estimation from a single RGB image; (ii) camera pose estimation; (iii) single-image novel view synthesis. *We conduct all experiments on indoor scenes in this paper*, as shown in Figure 1. For depth estimation, we train on Scannet (Dai et al., 2017). Our method significantly improves over previous self-supervised depth estimation approaches not only on the Scannet test set and also generalizes to NYU Depth V2 (Nathan Silberman & Fergus, 2012) better. For camera pose estimation, we use RealEstate10K (Zhou et al., 2018) following (Lai et al., 2021) and consistently achieve much better performance compared to previous approaches. For novel view synthesis from a single image input, we estimate the monocular depth using the depth encoder, construct

the multiplane NeRF, and then render another view with a given camera. On RealEstate10K (Zhou et al., 2018), our approach significantly improves over methods that learn without camera ground-truth and also outperform recent methods that learn with the ground-truth cameras (Wiles et al., 2020). To our knowledge, our method is **the first work that learns neural radiance fields on a large-scale dataset without camera ground truth**.

## 2. Related Work

**Novel View Synthesis and Neural Radiance Fields.** Learning-based novel view synthesis has been a long stand task. Researchers have studied on using explicit 3D representations including voxels (Jimenez Rezende et al., 2016; Kar et al., 2017; Tulsiani et al., 2017; Sitzmann et al., 2019a; Tung et al., 2019; Nguyen-Phuoc et al., 2019), depth maps (Wiles et al., 2020; Rockwell et al., 2021) and multiplane image (Zhou et al., 2018; Srinivasan et al., 2019; Tucker & Snavely, 2020; Li et al., 2021) for view synthesis. For example, Wiles et al. (2020) proposed to infer the depth map from the input image as an intermediate representation and perform rendering from another view for synthesis. Instead of using a single depth map, multiplane image (MPI) representation is utilized to explicitly model the occluded contents during view synthesis (Tucker & Snavely, 2020). Besides explicit 3D representations, recent work on using implicit representations have shown superior performance in view synthesis (Sitzmann et al., 2019b; Niemeyer et al., 2020). Following this line of research, NeRF and its subsequent works (Yu et al., 2021; Trevithick & Yang, 2021; Martin-Brualla et al., 2021; Schwarz et al., 2020; Wang et al., 2021c; Meng et al., 2021) have even achieved photo-realistic rendering results. While the original formulation is restricted to one single instance with the provided camera, recent extensions have made it available to generalize to multiple instances with camera ground-truths (Yu et al., 2021; Trevithick & Yang, 2021; Li et al., 2021; Chen et al., 2021; Wang et al., 2021b; 2022; Venkat et al., 2023) or training on **a single scene** without camera ground-truths (Wang et al., 2021c; Meng et al., 2021). For example, Yu et al. (2021) propose to leverage an encoder network to model the scene priors and train a generalizable NeRF on diverse scenes with given camera poses. On the other hand, Wang et al. (2021c) shows that the camera pose can be jointly optimized as learnable parameters with NeRF training. However, this approach only works on training NeRF for a single scene. None of the previous works can generalize to training on large-scale data and without cameras at the same time.

**Disentangled representations.** Disentangled representations aim to decompose complex visual data into several lower-dimensional individual factors that control different types of attributes. Common approaches to achieve dis-

entanglement include using Generative Adversarial Networks (Chen et al., 2016b; Huang et al., 2018; Karras et al., 2019; Lee et al., 2020; Zhu et al., 2018) and Autoencoders (Jha et al., 2018; Liu et al., 2020; Park et al., 2020; Pidhorskyi et al., 2020). For instance, Park et al. (2020) proposed an Autoencoder to disentangle texture from the structure by enforcing one component to encode co-occurrent patch statistics across different parts of the image. Besides learning from images, recently researchers have looked into using the temporal continuity in videos for learning disentangled representations (Denton et al., 2017; Minderer et al., 2019; Wiles et al., 2018; Xue et al., 2016; Lai et al., 2021). The most related work to our method is VideoAE (Lai et al., 2021), where an autoencoder network is proposed to disentangle the static 3D scene structure and camera motion from videos. However, their 3D structure is represented by deep voxel features, which cannot reveal the explicit scene geometric structure. The proposed MonoNeRF is able to directly infer depth as the scene representation, which can be directly used as a downstream application.

**Self-Supervised Depth Estimation.** Single image depth estimation has been widely studied in a supervised learning setting (Eigen et al., 2014; Laina et al., 2016; Kendall et al., 2017). However, with the absence of ground-truth depth or camera pose in most real-world data, self-supervised approaches using image reconstruction as the training signal without relying on neither depth nor camera annotations are proposed (Zhou et al., 2017; Vijayanarasimhan et al., 2017; Yin & Shi, 2018; Yang et al., 2018; Mahjourian et al., 2018; Gordon et al., 2019; Li et al., 2020). In this paper, we also follow the setting on learning without both depth and camera ground-truths and apply it on indoor scenes. Different from previous approaches, we show that depth can be learned by rendering with multiplane NeRF, which not only significantly improves depth estimation, but also allows better camera estimation and novel view synthesis results. Our work is also related to self-supervised learning of visual representations from videos (Agrawal et al., 2015; Han et al., 2019; Misra et al., 2016; Wang & Gupta, 2015; Wang et al., 2019; Jabri et al., 2020). However, instead of focusing on learning representations for recognition tasks, our work is more focused on scene geometric understanding for tasks including camera pose estimation, depth estimation, and novel view synthesis.

### 3. Method

In this work, MonoNeRF aims to learn generalizable NeRF representations from monocular videos in a self-supervised manner (**no camera pose and depth ground-truths**) in an autoencoder fashion. As multiple continuous frames from the video can reconstruct multiplane images for a given view (Tucker & Snavely, 2020), we adopt a variant

of NeRF (Li et al., 2021) which combines the discrete multiplane images into NeRF to create continuous multiplane neural radiance fields in our approach. The inputs to our model are video frames (3 frames in our experiments) that are nearby in a short period of time. The video frames are processed with the depth encoder and the camera pose encoder for the depth estimation and camera trajectory estimation respectively. In the decoding process, we construct the multiplane NeRF representation using the depth encoder feature and render using the estimated cameras. We minimize the reconstruction loss between the rendered frames and the input frames to learn the full model. MonoNeRF learns the disentanglement of the intermediate representations including the **depth feature** (which is used to predict depth) and the **camera pose**. We introduce the encoding process in sections 3.1 and 3.2, the decoding process in section 3.3, and the training details in section 3.4.

#### 3.1. Camera Pose Encoder

The camera pose encoder predicts the relative camera transformation between two input frames as shown at the bottom of Fig 2 (blue box). Specifically, given a source frame  $I_s$  and a target frame  $I_t$  as inputs, it computes the rotation matrix and translation matrix w.r.t the source view image. For an input sequence during training, we use the middle frame as the source view image and take the remaining frames before and after as target images. We follow the ResNet (He et al., 2016) architecture to design our encoder, which takes both frames as inputs (*i.e.*, stacked along the channel dimension leading to six input channels) and outputs a 6-dim vector as the 3D rotation and translation parameters. We formulate the camera encoder as,

$$\mathbf{T}_{s \rightarrow t} := [R, \mathbf{t}] = \mathcal{F}_{\text{traj}}([I_s, I_t]) \quad (1)$$

The estimated camera poses for all target images can construct a trajectory and then be used for target view synthesis in the decoder which will be discussed later.

#### 3.2. Monocular Depth Encoder

We design a separate encoder for monocular depth estimation from each single input frame, as shown in the upper part of Fig. 2 (green box). We adopt the network architecture from MnasNet (Tan et al., 2019) as the depth encoder network, which extracts feature maps with different resolution scales to predict the depth map. We formulate the depth encoder as,

$$\mathbf{D}_s = \mathcal{F}_{\text{dep}}(I_s) \quad (2)$$

Note that the raw output  $\mathbf{D}_s$  is the disparity map and needs to be converted to the depth map. The output monocular depth map is used as the intermediate representation to guide the construction of Multiplane NeRF.

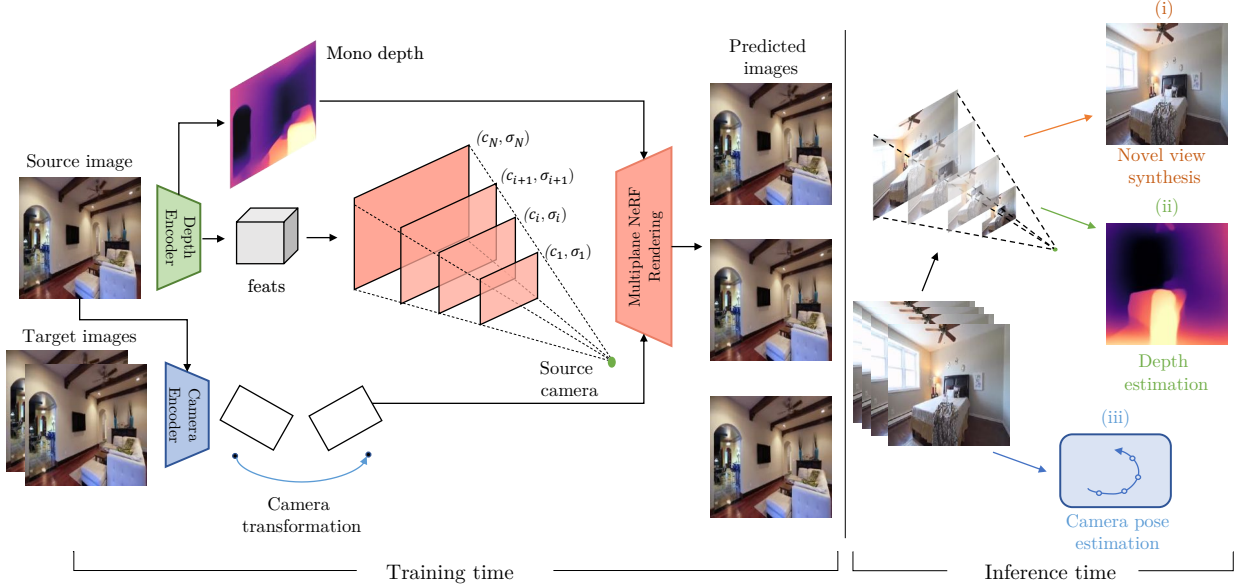

Figure 2: **Overview of proposed MonoNeRF.** Given a short clip of video, the camera encoder and depth encoder disentangle it into depth maps, neural representations, and relative camera trajectory. The Multiplane NeRF is utilized as the decoder to generate the target images according to the estimated camera pose. During training, the model is supervised via the reconstruction loss between the input frames and the generated ones. During testing, three downstream tasks, *i.e.* camera pose estimation, depth estimation, and novel view synthesis can be achieved within a single model.

### 3.3. Multiplane NeRF based Decoder

The disentanglement is learned via back-propagation from the differentiable decoder. To enable the optimization, we assume that the input video frames are taken from a short range of time scales, and the scene structure remains the same. This assumption provides supervision for our method to construct a Multiplane NeRF representation from a single image in our decoder, and use this representation to render the outputs. We first introduce the multiplane image representation, and then illustrate how to combine it with NeRF to perform rendering in our framework.

**Multiplane Images.** We first review Multiplane Images (MPIs) (Zhou et al., 2018), where an image is represented by a set of parallel planes of RGB- $\alpha$ ,  $\{(c_i, \alpha_i)\}_{i=1}^D$ , where  $c_i \in \mathbb{R}^{H \times W \times 3}$  are RGB values,  $\alpha_i \in \mathbb{R}^{H \times W \times 1}$  are the alpha values and  $D$  is the number of planes. Each plane corresponds to a specific disparity (inverse of depth) value  $d_i$  uniformly sampled from a predefined range  $[d_{\min}, d_{\max}]$ . Given the rotation matrix  $R$  and translation matrix  $\mathbf{t}$  from target to source view and the intrinsics matrix for source and target views  $K_s, K_t$ , we can generate the target-view image  $\hat{\mathbf{I}}_t$  and the disparity map  $\hat{\mathbf{D}}_s$  via the following steps. We use  $\mathbf{D}$  to denote the monocular depth directly estimated from the network, and  $\hat{\mathbf{D}}$  to denote the depth generated by rendering from MPI. First, the warping operation for the  $i$ -th plane from target to source view can be formulated as

the following,

$$\begin{bmatrix} u_s \\ v_s \\ 1 \end{bmatrix} \sim K_s (R - \mathbf{t}\mathbf{n}^T d_i) (K_t)^{-1} \begin{bmatrix} u_t \\ v_t \\ 1 \end{bmatrix} \quad (3)$$

where  $\mathbf{n}$  is the norm vector of the  $i$ -th plane and  $[u_s, v_s]$ ,  $[u_t, v_t]$  are coordinates in the source and target views respectively. The MPI representation of the target view can be obtained by warping each layer from the source viewpoint to the desired target viewpoint using Eq. 3. Then, the MPI representation under target view  $(c'_i, \alpha'_i)$  can be described as,

$$c'_i(u_t, v_t) = c_i(u_s, v_s) \quad \alpha'_i(u_t, v_t) = \alpha_i(u_s, v_s) \quad (4)$$

Finally, the RGB image and the disparity map under both the source view and target view can be obtained via the same compositing procedure proposed in (Zhou et al., 2018),

$$\begin{cases} \hat{\mathbf{I}}_s = \sum_{i=1}^D (c_i \alpha'_i \prod_{j=i+1}^D (1 - \alpha_j)) \\ \hat{\mathbf{D}}_s = \sum_{i=1}^D (d_i \alpha_i \prod_{j=i+1}^D (1 - \alpha_j)) \end{cases} \quad (5)$$

$$\begin{cases} \hat{\mathbf{I}}_t = \sum_{i=1}^D (c'_i \alpha'_i \prod_{j=i+1}^D (1 - \alpha'_j)) \\ \hat{\mathbf{D}}_t = \sum_{i=1}^D (d_i \alpha'_i \prod_{j=i+1}^D (1 - \alpha'_j)) \end{cases} \quad (6)$$

**Multiplane NeRF** . Going beyond RGB images, we generalize the representations by introducing NeRF as (Li et al., 2021), namely Multiplane NeRF. Different from MPI which consists of multiple planes of RGB- $\alpha$  images at sparse and discrete depths, the Multiplane NeRF achieves continuous representation of 3D scenes by predicting RGB- $\alpha$  images at any arbitrary depth. Formally, the image is represented by  $\{(c_i, \sigma_i)\}_{i=1}^D$ , where  $\sigma_i$  is the volume density of the  $i$ -th plane. We follow a similar setting to construct the Multiplane NeRF representation as our decoder to generate the novel view images. Specifically, we extract the intermediate representation from the *monocular depth encoder* (gray cube in Fig. 2) as the image feature for  $\mathbf{I}_s$ . We combine this feature with a disparity level  $d_i$  as the inputs for an internal encoder-decoder module, which outputs the RGB image  $c_i$  and the density map  $\sigma_i$  as a 4-channel map  $\{(c_i, \sigma_i)\}$  (multiple orange planes in Fig. 2). We have different planes of  $\{(c_i, \sigma_i)\}$  given different disparity  $d_i$ , and we use positional encoding to encode each  $d_i$ . The  $i$ -th plane for the Multiplane NeRF representation is formulated as,

$$\{c_i, \sigma_i\} = \mathcal{F}_{\text{mpi}}(\mathbf{I}_s, \text{PE}(d_i)) \quad (7)$$

Note we only need to run the depth encoder once to extract the image feature for  $\mathbf{I}_s$ . To reconstruct one target view, given the camera trajectory obtained from the *camera pose encoder* (blue module in Fig 2), we first compute the new RGB and density values on the target view  $(c'_i, \sigma'_i)$  using homography warping described in Eq. 3, then replace the alpha map  $\alpha$  and the compositing operation in Eq. 5 by the volume density  $\sigma$  and the naive rendering procedure used in (Mildenhall et al., 2020) to obtain the image and the disparity map. The advantages of multiplane NeRF over the vanilla NeRF include: (i) it builds the frustum from a single image; (ii) it has a better generalization ability allowing training on large-scale data, which makes it more feasible than NeRF as the decoder in our autoencoder-like architecture.

### 3.4. Supervision with RGB

Our model is trained in a self-supervised manner by reconstructing multiple video frames as shown in Fig. 2. During training, we select the center frame of  $N$ -frame clip ( $N = 3$  in our experiments) as the source view image  $\mathbf{I}_s$ . We use the depth encoder to estimate the monocular depth  $\mathbf{D}_s$  for the source view. We use the camera encoder taking the source view image  $\mathbf{I}_s$  and the target view image  $\mathbf{I}_t$  as the inputs to obtain the relative camera pose  $(R, t)$ . Together with the depth encoder feature (gray box in Fig. 2) and the estimated camera, we can construct the Multiplane NeRF representation and render the target view  $(\hat{\mathbf{I}}_t, \hat{\mathbf{D}}_t)$  as the outputs. The autoencoder is supervised by comparing the rendered target image  $\hat{\mathbf{I}}_t$  and the ground-truth target image  $\mathbf{I}_t$ . However, a direct reconstruction objective can easily lead to trivial

solutions given both depth and camera ground truths are not provided in training. We propose **two key technical contributions** including auto-scale calibration and new loss functions to enable successful disentanglement of depth and camera pose.

#### 3.4.1. AUTO SCALE CALIBRATION

Recall that our Multiplane NeRF is built upon a single image, this can lead to the scale ambiguity issue. As explained in (Tucker & Snavely, 2020; Li et al., 2021), each training sequence can be considered equally valid when we scale down or up the world coordinate by any constant value. To tackle this issue, (Li et al., 2021) and (Tucker & Snavely, 2020) propose to use Structure-from-Motion (SfM) to compute **camera pose** and the **depth** (sparse point cloud), where both are at the same scale. The calibration procedure is to adjust the camera pose by comparing the depth from SfM and the rendered depth map from Multiplane NeRF. However, the requirement of running SfM in training and testing is time-consuming and it does not always succeed.

In this paper, we propose to overcome the limits of SfM, and use the encoders to estimate the camera pose  $\mathbf{T}_{s \rightarrow t}$  (Eq. 1) and disparity map  $\mathbf{D}_s$  (Eq. 2). In this case, none of the **camera pose**  $\mathbf{T}_{s \rightarrow t}$ , the **disparity map**  $\mathbf{D}_s$  and the **NeRF rendered disparity map**  $\hat{\mathbf{D}}_s$  are at the same scale initially. We need to calibrate all three together at the same time in the following two steps.

(i) First, we encourage the rendered disparity map  $\hat{\mathbf{D}}_s$  to be consistent with the disparity prediction  $\mathbf{D}_s$  by minimizing the L1 distance between them. In detail, we first convert the disparity map into the depth map and then compute the pixel-wise L1 distance between them,

$$\mathcal{L}_{\text{consist}} = \frac{1}{HW} \sum \left| \frac{1}{\mathbf{D}_s} - \frac{1}{\hat{\mathbf{D}}_s} \right|_1 \quad (8)$$

The above step aligns the rendered depth result with the monocular depth estimation result.

(ii) Meanwhile, we need to guarantee that the monocular depth estimation and the estimated camera pose are on the same scale. We achieve this goal via applying a photometric reprojection loss (Godard et al., 2019) between the original source image  $\mathbf{I}_s$  and the synthesized source image  $\mathbf{I}_{t \rightarrow s}$ , obtained by projecting pixels from  $\mathbf{I}_t$  onto  $\mathbf{I}_s$  given the predicted monocular depth  $\mathbf{D}_s$ , camera transformation  $\mathbf{T}_{s \rightarrow t}$  and the camera intrinsic  $\mathbf{K}_s$ .

$$\mathcal{L}_{\text{reproj}} = \frac{1}{HW} \sum |\mathbf{I}_s - \mathbf{I}_{t \rightarrow s}|_1 \quad (9)$$

where  $\mathbf{I}_{t \rightarrow s} = \mathbf{I}_t \langle \text{proj}(\mathbf{D}_s, \mathbf{T}_{s \rightarrow t}, \mathbf{K}_s) \rangle$ .

These two steps can achieve the calibration among the camera pose  $\mathbf{T}_{s \rightarrow t}$ , the disparity map  $\mathbf{D}_s$  and the NeRF rendered

disparity map  $\hat{\mathbf{D}}_s$  by enforcing the alignment between the synthesized disparity map  $\hat{\mathbf{D}}_s$  and the estimated disparity map  $\mathbf{D}_s$  as well as the alignment between camera pose  $\mathbf{T}_{s \rightarrow t}$  and the estimated disparity map  $\mathbf{D}_s$  simultaneously.

### 3.4.2. LOSS FUNCTIONS

In addition to the calibration, we also adopt three loss functions: RGB L1 loss  $\mathcal{L}_{L1}$ , RGB SSIM loss  $\mathcal{L}_{SSIM}$  and edge-aware disparity map smoothness loss  $\mathcal{L}_{smooth}$  as described in (Tucker & Snavely, 2020). The RGB L1 loss and SSIM loss (Wang et al., 2004) are defined as,

$$\mathcal{L}_{L1} = \frac{1}{HW} \sum |\hat{\mathbf{I}}_t - \mathbf{I}_t| \quad (10)$$

$$\mathcal{L}_{SSIM} = 1 - \text{SSIM}(\hat{\mathbf{I}}_t, \mathbf{I}_t) \quad (11)$$

Both losses aim at matching the synthesized target image with the ground-truth one. Both  $\hat{\mathbf{I}}_t$  and  $\mathbf{I}_t$  are RGB images with the size of  $H \times W$ . Meanwhile, we impose an edge-aware smoothness loss on the synthesized disparity map to align the edge and smoothness region between the disparity map and the original image (Godard et al., 2017; 2019; Tucker & Snavely, 2020; Li et al., 2021),

$$\mathcal{L}_{smooth} = |\partial_x \frac{\hat{\mathbf{D}}_s}{\mathbf{D}_s}| \exp^{-|\partial_x \mathbf{I}|} + |\partial_y \frac{\hat{\mathbf{D}}_s}{\mathbf{D}_s}| \exp^{-|\partial_y \mathbf{I}|} \quad (12)$$

where  $\partial_x$  and  $\partial_y$  are image gradients and  $\bar{\mathbf{D}}_s$  is the mean value of the disparity map  $\mathbf{D}_s$ . Overall, together with the scale calibration losses, the total is:

$$\mathcal{L} = \lambda_{L1} \mathcal{L}_{L1} + \lambda_{SSIM} \mathcal{L}_{SSIM} + \lambda_{smooth} \mathcal{L}_{smooth} + \lambda_{consist} \mathcal{L}_{consist} + \lambda_{reproj} \mathcal{L}_{reproj} \quad (13)$$

## 4. Experiments

We empirically evaluate MonoNeRF and compare it to the existing approaches on three different tasks: monocular depth estimation, camera pose estimation, and single image novel view synthesis. We perform evaluations on indoor scenes. Compared to outdoor street views, indoor scenes have more structural variance and are more commonly used for evaluating all three tasks together.

### 4.1. Implementation Details

In the pre-processing step, we resize all images to the resolution of  $256 \times 256$  for both training and testing. During training, we randomly sample 3 frames per sequence with the interval of 5 as the input to ensure the camera motion is large enough. The number of planes  $D$  is set to 64 and the range of camera frustum is predefined as  $[0.2, 20]$ . We train our model end-to-end using a batch size of 4 with an Adam optimizer for 10 epochs. The initial learning rate is set to 0.0001 and is halved at 4, 6, 8 epochs. We empirically

set the balance parameters  $\lambda_{L1}$ ,  $\lambda_{SSIM}$ ,  $\lambda_{smooth}$ ,  $\lambda_{consist}$  and  $\lambda_{reproj}$  in Eq. 13 to 1.0, 1.0, 1.0, 0.01, 1.0 and 30, respectively. All configurations and hyperparameters are shared for all experiments over three tasks unless specified.

### 4.2. Depth Estimation

We evaluate our depth estimation results on two standard benchmarks: ScanNet (Dai et al., 2017) and NYU-depth V2 (Nathan Silberman & Fergus, 2012). We use the synthesized (rendered) depth map as our prediction result and evaluated it by standard metrics introduced in (Eigen et al., 2014), including: absolute depth error (abs err), absolute relative depth error (abs rel), absolute log depth error (log10), squared relative error (sq rel), RMSE and inlier-ratio with threshold ( $\sigma$ ).

Given a testing frame, instead of using the monocular depth estimation results, we obtain the depth map via rendering with neural representation learnt from MonoNeRF. Comparing with the monocular depth predictions, the rendered depth maps are always more smooth. Before evaluation, we first align predictions with the ground truths for scale ambiguity issue, which is a common strategy for monocular depth estimation (Tucker & Snavely, 2020; Yin et al., 2021).

For the experiment on the ScanNet (Dai et al., 2017), we train our framework with all training sequences and evaluate it on all testing sequences released in the official test split. We first compare our model with several fully supervised methods that trained with ground-truth depth supervision: MVDepthNet (Wang & Shen, 2018), GPMVS (Hou et al., 2019), DPSNet (Im et al., 2019) and Atlas (Murez et al., 2020). We directly borrow the performance reported in their paper and list them in Table 1. Note that most of these methods are based on MVS with at least two images as input while our work only requires a single image as input. Without any depth ground truths, our approach still achieves a comparable result with some state-of-the-art. Meanwhile, compared to MonodepthV2 (Godard et al., 2019) which also only requires RGB supervision as ours, our method achieves much better performance.

Beyond ScanNet (Dai et al., 2017), we also evaluate the depth estimation performance on NYU Depth V2 (Nathan Silberman & Fergus, 2012). For a fair com-

parison, we train the model only with RealEstate10K (Zhou et al., 2018) training data as suggested in (Tucker & Snavely, 2020; Li et al., 2021) and report the results in Table 2. We split the existing method into three groups: (i) the depth supervision model: including Depth in the Wild (Chen et al., 2016a)(DIW), MegaDepth (Li & Snavely, 2018), 3DKenBurns (Niklaus et al., 2019) and MiDaS (Ranftl et al., 2020); (ii) the RGB supervision model with camera pose; including MPI (Tucker & Snavely, 2020) and MINE (Li et al., 2021); and (iii) the RGB supervision model without camera pose, including MonodepthV2 (Godard et al., 2019) and Manydepth (Watson et al., 2021). Notably, compared to MiDaS (Ranftl et al., 2020) trained across 10 different datasets with depth supervision, we achieve comparable performance. Although our method is slightly worse than MINE (Li et al., 2021), they utilize ground-truth camera poses for training while we do not. Compared with the approaches without neither depth supervision nor camera poses, our approach significantly outperforms them by a large margin.

### 4.3. Camera Pose Estimation

We perform camera pose trajectory estimation and evaluate its performance on RealEstate10K (Zhou et al., 2018). Following (Lai et al., 2021), we use 1,000 30-frames video clips from RealEstate10K testing data to construct the testing set. For each video clip, we take a pair of images as input and estimate the relative pose between them and repeat this step sequentially through the whole video to obtain

the full trajectory. Since the model only estimates the relative pose in the world coordinate defined in our model, we adopt a post-processing step for alignment between the predicted camera trajectory and the SfM trajectory provided by RealEstate10K (Zhou et al., 2018) via the Umeyama algorithm (Umeyama, 1991). We evaluate the Absolute Trajectory Error (ATE) over testing videos and compare it with the state-of-the-art methods in Table 3.

SfMLearner (Zhou et al., 2017) and P<sup>2</sup>Net (Yu et al., 2020) are two works related to ours, which borrow similar ideas from traditional SfM and optimize the camera trajectory and depth map jointly. Our approach outperforms them by a large margin. For instance, the RMSE is reduced from 0.055 to 0.011 which is about a 80% improvement. In addition, our approach is superior compared to the COLMAP (Schönberger et al., 2016) based on the SfM pipeline. Especially for the videos with slow and little camera movement, COLMAP (Schönberger et al., 2016) can hardly work well and always requires plenty of frames to process leading to a much longer inference time. Finally, a similar improvement can be also found when comparing to VideoAE (Lai et al., 2021), which is a recent work on the disentanglement of camera motion and 3D structure. The qualitative result is shown in Fig. 3

### 4.4. Novel View Synthesis

Our approach generates novel view images by rendering the Multiplane NeRF representation into target views. Following the setting of (Wiles et al., 2020; Lai et al., 2021), we evaluate the novel view synthesis on RealEstate10K (Zhou et al., 2018), which is a large-scale walkthrough video dataset with both indoor and outdoor scenes. During testing, we follow two test splits provided by SynSin (Wiles et al., 2020) and MINE (Li et al., 2021). For evaluation, we randomly sample 5 source frames from each testing sequence and sample target frames that are 5 frames apart from the source frames. We measure the similarity scores by PSNR, SSIM (Wang et al., 2004), and perceptual similarity

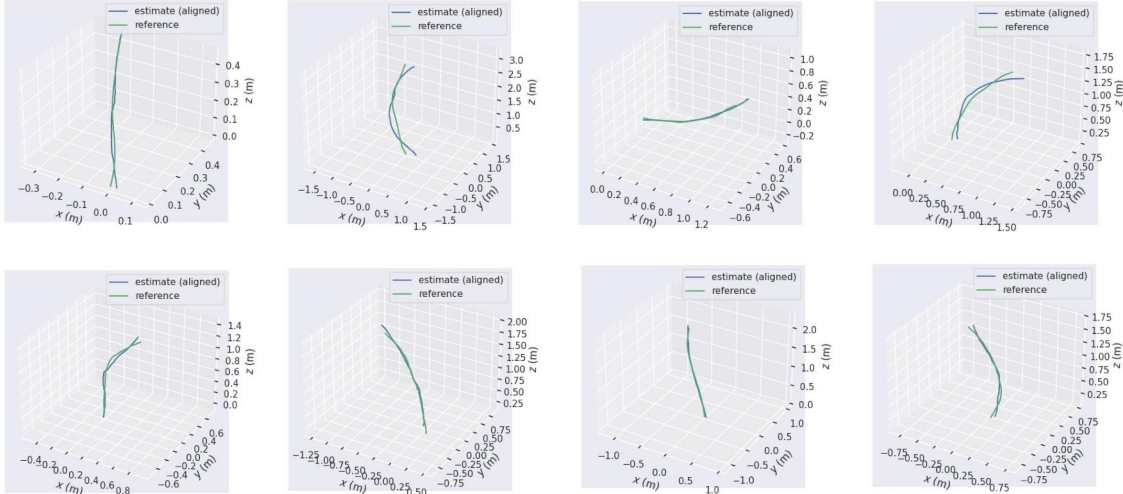

Figure 3: Visualization of estimated camera trajectory on RealEstate10K (Zhou et al., 2018). The green trajectory indicates the ground-truth camera poses while the blue one indicates the estimated poses.

Table 4: Comparison of novel view synthesis task on RealEstate10K. We follow the standard metrics of PSNR, SSIM, and Perc Sim (Wiles et al., 2020). The number xx\* represents the LPIPS metric using the implementation of (Zhang et al., 2018). †StereoMag makes use of 2 images as input. ‡MPI and ‡MINE use sparse point clouds as the additional supervision signal during training.

with VGG (Simonyan & Zisserman, 2014) features. Note that there are two different implementations to calculate the perceptual similarity used in SynSin and MINE, the latter one is also known as LPIPS (Zhang et al., 2018). Table 4 summarizes the novel view synthesis performance over different methods. Compared to single-image view synthesis algorithms, for instance, Synsin (Wiles et al., 2020), our method can achieve comparable or better performance, even though our method does not require camera pose ground truths while other methods do. For instance, our method is better than Synsin (Wiles et al., 2020) over all three metrics. Some qualitative results are shown in Fig. 4 and more can

calib.	PSNR↑	SSIM↑	LPIPS↓
✗	21.46	0.677	0.289
✓	<b>26.68</b>	<b>0.863</b>	<b>0.143</b>

#D	PSNR↑	SSIM↑	LPIPS↓
64	26.68	0.863	0.143
32	26.56	0.861	0.141
16	26.65	0.861	0.144

Table 6: Novel view synthesis on RealEstate10K with the different number of planes.

be found in the supplementary.

Compared with MPI (Tucker & Snavely, 2020) and MINE (Li et al., 2021) where similar 3D representations are adopted, our approach is slightly worse on PSNR and SSIM. We believe this inferior performance is reasonable since they rely on the ground-truth camera pose and the sparse points obtained by COLMAP (Schönberger et al., 2016) during training and testing. On the other hand, our approach easily outperforms all existing methods of training without the camera pose. Some qualitative results are shown in Fig. 4 and more can be found in the supplementary material.

### 4.5. Ablation Study

We find the performance of three tasks are aligned in our experiments, thus we report the ablation mainly based on the novel view synthesis task here.

**Auto scale calibration.** We show the effectiveness of auto-calibration (Sec. 3.4.1) by conducting an experiment w./w.o the calibration step. As shown in Table 5, the novel view synthesis performance drops dramatically without the auto

Figure 4: Visualization of depth and novel view images on RealEstate10K. We compare our method with Synsin. Despite they share similar quality of generated images, our depth output is much more accurate.

ratio	PSNR $\uparrow$	SSIM $\uparrow$	LPIPS $\downarrow$

Synsin (Wiles et al., 2020)	0.91	1.81	2.08
MINE (Li et al., 2021)	0.19	0.18	<b>0.34</b>
MonoNeRF	<b>0.17</b>	<b>0.09</b>	0.39

Table 8: Generalization ability of novel view synthesis task and depth estimation task. We pretrain our model on the RealEstate10K and evaluate on the 100 30-frames clips of ScanNet.

scale calibration, *i.e.*, more than 5% on PSNR, which indicates this calibration step is beneficial to scale-invariant synthesis.

**Number of planes.** We compare our default model with different numbers of planes used in Multiplane NeRF as listed in Table 6. We found that our approach is not so sensitive to the number of planes, but in general, our default setting achieves the best performance.

**Amount of training data.** We analyze the effect of using

different fractions of training data. We uniformly sample every 20% fraction of RealEstate10K (Zhou et al., 2018) training data and evaluate the performance on the same test set. As reported in Table 7, with more training data, the quality of generated images is getting better.

**Generalization ability.** To show the generalization ability of our model, we utilize the model pretrained on RealEstate10K and evaluate the performance of novel view synthesis and depth estimation on ScanNet. As illustrated in Table 8, our model can achieve on par or even better results on both two tasks.

## 5. Conclusion

We present an autoencoder architecture that disentangles video into camera motion and depth map via the camera encoder and the depth encoder. And the Multiplane NeRF is utilized as the decoder to represent the 3D scene. We further introduce an auto-scale calibration strategy to learn the disentanglement representation even with the camera pose. With the powerful 3D representation, we show our model enables camera pose estimation, depth estimation, and novel view synthesis. Our model achieves on-par or even better results on three tasks compared to approaches with the ground-truth camera or depth during training.
